Newborn Resuscitation

ANUP KATHERIA AND NEIL N. FINER

KEY POINTS

- Adequate preparation for newborn resuscitation ensures that care can be provided in a timely and competent manner.
- Avoiding early umbilical cord clamping following delivery may have a significant impact on newborn outcomes.
- The use of additional monitoring (such as electrocardiography, carbon dioxide detection, and respiratory function) can be helpful during resuscitation.

The transition from fetal to neonatal life is a dramatic and complex process involving extensive physiologic changes that are most obvious at the time of birth. Individuals who care for newborns must monitor the progress of this transition and be prepared to intervene when necessary. In most births this transition occurs without a requirement for any significant assistance. However, when the need for intervention arises, the presence of providers skilled in neonatal resuscitation can be lifesaving. Each year approximately 4 million children are born in the United States ([Martin et al., 2008](#)), and more than 30 times as many are born worldwide. It is estimated that approximately 5%–10% of all births will require some form of resuscitation beyond basic care, making neonatal resuscitation the most frequently practiced form of resuscitation in medical care. Throughout the world approximately 1 million newborn deaths are associated with birth asphyxia ([Lawn et al., 2005](#)). While early effective newborn resuscitation will not eliminate all early neonatal deaths, such intervention will save many lives and significantly reduce subsequent morbidities.

Attempts to revive nonbreathing newborns immediately after birth have been made throughout recorded time, with references in the literature, religion, and early medicine. Although the organization and sophistication have changed, the basic principle and goal of initiating breathing has remained constant throughout time. It has been just in the last 30 years that more attention has been focused on the process of neonatal resuscitation.

Resuscitation programs in other areas of medicine were initiated in the 1970s in an effort to improve knowledge of effective resuscitation and provide an action plan for early responders. The first such program (1974) was focused on adult cardiopulmonary resuscitation. These programs then began increasing in complexity and becoming

more specific to different types of resuscitation needs. With the collaboration of the American Heart Association and the American Academy of Pediatrics, the Neonatal Resuscitation Program (NRP) was initiated in 1987—designed to address the specific needs of the newborn. Recent editions of the NRP textbook ([Kattwinkel 2006](#)) contained several revisions, including specific recommendations for the preterm newborn. Various groups throughout the world also provide resuscitation recommendations that may be more specific to the practices in certain regions. An international group of scientists, the International Liaison Committee on Resuscitation (ILCOR), meets on a regular basis to review available resuscitation evidence for all the different areas of resuscitation and puts forth a summary of its review ([Chamberlain, 2005](#)). The most recent recommendation by ILCOR ([Perlmán et al., 2015](#)) and the recommendations in the seventh edition of the NRP textbook (2016) are outlined in this review.

The overall goal of the NRP is similar to that of other resuscitation programs in that it intends to teach large groups of individuals of varied backgrounds the principles of newborn resuscitation and to provide an action plan for providers. Similarly, a satisfactory end result of resuscitation would be common to all forms of resuscitation: namely, to provide adequate tissue oxygenation to prevent tissue injury and restore spontaneous cardiopulmonary function. However, when one is comparing neonatal resuscitation with other forms of resuscitation, there are two distinctions. First, the birth of a child is a more predictable occurrence than most events requiring resuscitation in an adult such as an arrhythmia or a myocardial infarction. While not every birth will require “resuscitation,” it is more reasonable to expect that skilled individuals can be present when the need for neonatal resuscitation arises. It is possible to anticipate with some accuracy which newborns will more likely require resuscitation on the basis of perinatal factors and thus allow time for preparation.

The second distinction of neonatal resuscitation compared with other forms of resuscitation involves the unique physiology involved in the normal transition from fetal to neonatal life. The fetus exists in the protected environment of the uterus, where temperature is closely controlled, the lungs are filled with fluid, continuous fetal breathing is not essential, and the gas exchange organ is the placenta. The transition that occurs at birth requires the newborn to increase heat production, initiate continuous breathing, replace the lung fluid with air/oxygen, and significantly increase pulmonary blood

flow so that gas exchange can occur in the lungs. The expectations for this transitional process and knowledge of how to effectively assist the process help guide the current practice of newborn resuscitation.

Transition From Fetal to Extrauterine Life

While the complete transition from fetal to extrauterine life is complex and much more intricate than can be discussed in a few short paragraphs, basic knowledge of these processes will contribute to the understanding of the rationale for resuscitation practices. The key elements necessary for a successful transition to extrauterine life involve changes in thermoregulation, respiration, and circulation. In utero, the fetal core temperature is approximately 0.5°C greater than the mother's temperature (Gunn and Gluckman, 1983). Heat is produced by metabolic processes and is lost over this small temperature gradient through the placenta and skin (Gilbert et al., 1985). After birth the temperature gradient between the newborn and the environment becomes much greater, and heat is lost through the skin by radiation, convection, conduction, and evaporation. The newborn must begin producing heat through other mechanisms, such as lipolysis of brown adipose tissue (Dawkins and Scopes, 1965). If heat is lost at a pace greater than it is produced, the newborn will become hypothermic. Preterm newborns are at particular risk because of increased heat loss through immature skin, a greater surface area to body weight ratio, and decreased brown adipose tissue stores.

The fetus lives in a fluid-filled environment, and the developing alveolar spaces are filled with lung fluid. Lung fluid production decreases in the days before delivery (Kitterman et al., 1979), and the remainder of lung fluid is reabsorbed into the pulmonary interstitial spaces after delivery (Bland, 1988). As the newborn takes its first breaths after birth, a negative intrathoracic pressure of approximately $50\text{ cmH}_2\text{O}$ is generated (Vyas et al., 1986). The alveoli become filled with air, and with the help of pulmonary surfactant, the lungs retain a small amount of air persisting at the end of exhalation that is known as the functional residual capacity (FRC). Although the fetus makes breathing movements in utero, these efforts are intermittent and are not required for fetal gas exchange. Continuous spontaneous breathing is maintained after birth by several mechanisms, including the activation of chemoreceptors, the decrease in the levels of hormones that inhibit respirations, and the presence of natural environmental stimulation.

Spontaneous breathing can be suppressed at birth for several reasons, most critical of which is the presence of acidosis secondary to compromised fetal circulation. The natural history of the physiologic responses to asphyxia and acidosis has been described by researchers evaluating animal models. Dawes (1968) described the breathing response to acidosis in different animal species. He noted that when the pH is decreased, animals typically have a relatively short period of apnea followed by gasping. The gasping pattern then increases in rate until breathing ceases again for a second period of apnea. The physiologic effects that occur with worsening acidosis are noted in Fig. 24.1. Dawes also noted that the first period, or primary apnea, could be reversed with stimulation, while the second period, secondary or terminal apnea, required assisted ventilation to ultimately establish spontaneous breathing. The first sign of improvement was noted to be an increase in heart rate. Further recovery was noted when the newborn begins gasping again. The secondary period of apnea differs in duration depending on the duration of asphyxia and the degree of acidosis. In the clinical situation the exact timing of the onset of acidosis is generally

• **Fig. 24.1** The Sequence of Cardiopulmonary Changes With Asphyxia and Resuscitation. Time is on the horizontal axis. Asphyxia progresses from left to right; resuscitation proceeds from right to left. Units of time are not given. If there is complete interruption of respiratory gas exchange, the entire process of asphyxia from extreme left to right could occur in approximately 10 minutes. It could take much longer with an asphyxiating process that only partly interrupts gas exchange or does so completely but only for repeated brief periods. With resuscitation, the process reverses, beginning at the point to which asphyxia has proceeded. The blue dotted line is the reversal of asphyxia with resuscitation. (Modified from Dawes G. *Foetal and Neonatal Physiology*. Chicago: Year Book; 1968; and Avery GN. *Neonatology*. Philadelphia: JB Lippincott; 1987.)

unknown, and therefore any observed apnea may be either primary or secondary. This is the basis of the resuscitation recommendation that stimulation may be attempted in the presence of apnea, but if it is not quickly successful, assisted ventilation should be initiated promptly. Without the presence of acidosis a newborn may also develop apnea because of recent exposure to respiratory-suppressing medications such as narcotics, anesthetics, and magnesium. These medications when given to the mother cross the placenta and depending on the time of administration and dose may depress the newborn's respiratory drive.

Fetal circulation is unique because gas exchange occurs in the placenta. In the fetal heart, oxygenated blood returning via the umbilical vein is mixed with deoxygenated blood from the superior vena cava and inferior vena cava and is differentially distributed throughout the body. The most oxygenated blood is directed toward the brain, while the most deoxygenated blood is directed toward the placenta. Thus blood returning from the placenta to the right atrium is preferentially streamed via the foramen ovale to the left atrium and left ventricle and then to the ascending aorta, providing the brain with the most oxygenated blood. Fetal channels, including the ductus arteriosus and foramen ovale, allow most blood flow to bypass the lungs with their intrinsically high vascular resistance,

• **Fig. 24.2** Fetal Circulation. Oxygenated blood leaves the placenta by way of the umbilical vein (vessel without stippling). The blood flows into the portal sinus in the liver (not shown), and a variable portion of it perfuses the liver. The remainder passes from the portal sinus through the ductus venosus into the inferior vena cava, where it joins blood from the viscera (represented by the kidney, gut, and skin). Approximately half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood. This relatively well oxygenated blood (light stippling) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right ventricle (blood in the right atrium and ventricle has little oxygen, which is denoted by heavy stippling). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA), so the descending aorta's blood has less oxygen (heavy stippling) than blood in the ascending aorta (light stippling). (From Avery GN. *Neonatology*. Philadelphia: JB Lippincott; 1987.)

and as a result pulmonary blood flow is approximately 8% of the total cardiac output. In the mature postnatal circulation the lungs must receive 100% of the cardiac output. When the low-resistance placental circulation is removed after birth, the newborn's systemic vascular resistance increases, while the pulmonary vascular resistance begins to fall as a result of pulmonary expansion, increased arterial and alveolar oxygen tension, and local vasodilators. These changes result in a dramatic increase in pulmonary blood flow. The average fetal oxyhemoglobin saturation as measured in fetal lambs is approximately 50% (Nijland et al., 1995) but ranges in different sites within the fetal circulation between 20%–80% (Teitel, 1988). The oxyhemoglobin saturation rises gradually over the first 5–15 minutes of life to 90% or greater as the air spaces are cleared of fluid. Diagrams of the blood flow patterns in the fetus and normally transitioning newborn are shown in Figs. 24.2–24.3. In the face of poor transition secondary to asphyxia, meconium aspiration,

• **Fig. 24.3** Circulation in the Normal Newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow increases and left atrial and systemic arterial pressures increase, while pulmonary arterial and right-sided heart pressures decrease. When the left atrial pressure exceeds the right atrial pressure, the foramen ovale closes so that all of the inferior and superior vena cava blood leave the right atrium, enter the right ventricle, and are pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary arterial pressure, flow through the ductus arteriosus becomes left-to-right, and the ductus arteriosus constricts and closes. The course of the circulation is the same as in the adult. (From Avery GN. *Neonatology*. Philadelphia: JB Lippincott; 1987.)

pneumonia, or extreme prematurity, the lungs may not be able to develop efficient gas exchange, and thus the oxygen saturation may not increase as expected. In addition, in some situations the normal reduction in pulmonary vascular resistance may not fully occur, resulting in persistent pulmonary hypertension and decreased effective pulmonary blood flow with continued right to left shunting through the aforementioned fetal channels. This will lead to persistent hypoxemia and potentially to significant newborn illness requiring intensive care until the circulatory pattern adjusts to extrauterine life. The circulatory pattern associated with poor transition is noted in Fig. 24.4.

Environment and Preparation

The environment in which the newborn is born should facilitate the transition to neonatal life as much as possible and should be able to readily accommodate the needs of a resuscitation team when necessary. Hospitals differ in their approach to the details of how to prepare for resuscitation. For example, some hospitals have a separate room designated for resuscitation where the newborn will be taken after birth, while others have the delivery room adjacent to the neonatal intensive care unit (NICU), and the newborn is resuscitated in the NICU if necessary. Hospitals may

• **Fig. 24.4** Circulation in an Asphyxiated Newborn With Incomplete Expansion of the Lungs. Pulmonary vascular resistance is high, pulmonary blood flow is low (normal number of pulmonary veins), and flow through the ductus arteriosus is high. With little pulmonary arterial flow, left atrial pressure decreases below right atrial pressure, the foramen ovale opens, and vena cava blood flows through the foramen into the left atrium. Partially venous blood goes to the brain via the ascending aorta. The blood of the descending aorta that goes to the viscera has less oxygen than that of the ascending aorta (*heavy stippling*) because of the reverse flow through the ductus arteriosus. Therefore the circulation is the same as in the fetus, except that there is less well-oxygenated blood in the inferior vena cava and umbilical vein. (From Avery GN. *Neonatology*. Philadelphia: JB Lippincott; 1987.)

bring all the necessary equipment into the delivery room when resuscitation is expected or may have every delivery room already equipped for any resuscitation. Wherever the resuscitation will happen, a few key elements must be considered. The room should be warm enough to prevent excessive newborn heat loss, bright enough for assessment of the newborn's clinical status, and large enough to accommodate the necessary personnel and equipment to care for the baby.

When no added risks to the newborn are identified, term births frequently occur without the attendance of a specific neonatal resuscitation team. However, it is recommended that one individual be present who is responsible only for the newborn and can quickly alert a neonatal resuscitation team if necessary. Even the best neonatal resuscitation triage systems will not anticipate the need for resuscitation in all cases. A review found that when a risk-based determination of neonatal resuscitation team attendance at deliveries was used, 22% of newborns at attended deliveries required at least assisted ventilation (Aziz et al., 2008). These investigators found that the most significant risk factors were preterm birth, emergency cesarean delivery, and meconium-stained amniotic fluid. Other significant risk factors for the need for resuscitation are listed in

TABLE 24.1 Risk Factors for Neonatal Resuscitation

| Maternal Factors | Fetal Factors | Intrapartum Factors |
|-------------------------------|---------------------|---|
| Maternal hypertension | Preterm delivery | Opiates in labor |
| Maternal infection | Breech presentation | Rupture of membranes >18 h |
| Multiple gestations (preterm) | Shoulder dystocia | Meconium-stained amniotic fluid |
| | | Nonreassuring fetal heart rate patterns |
| | | Emergency cesarean delivery |
| | | Prolapsed cord |

Data from Aziz K, Chadwick M, Baker M, Andrews E. Ante- and intra-partum factors that predict increased need for neonatal resuscitation. *Resuscitation*. 2008;79(3):444–452.

Table 24.1. Antenatal determination of risk allows the resuscitation team to be present for the delivery and to be more thoroughly prepared for the situation.

The composition of the neonatal resuscitation team will differ tremendously among institutions. Probably the most important factor in how well a team functions is how the team has prepared for the delivery. Preparation involves both the immediate tasks of readying equipment and personnel for an individual situation and the more broad institutional preparation of training team members and providing appropriate space and equipment. We believe that when there is a strong suspicion that the newborn will be born in a compromised state, a minimum of three team members should be present, including one member with significant experience in leading neonatal resuscitations.

Each team member has assigned tasks that are performed on a regular basis. The leader is expected to ensure that the appropriate interventions are performed and that they are performed well. All team members are encouraged and expected to speak up if a problem is noticed or if they believe an alternative course would be beneficial. It seems logical that teams that regularly work together and divide tasks in a routine manner will have a better chance of functioning smoothly during a critical situation.

Institutions can facilitate team readiness with regular review of practices and mock codes or simulator training to practice uncommon scenarios. In our institution, Sharp Mary Birch Hospital for Women & Newborns, we review recorded resuscitations monthly with representatives from all disciplines involved in the resuscitation team. This is done as a quality assurance procedure and allows ongoing identification of areas needing improvement (Carbine et al., 2000). Additionally, this practice provides an opportunity for education and discussion about potential solutions to repetitive problems of newborn resuscitation. We have also instituted a supplemental training program for our pediatric trainees to obtain experience in a preclinical situation (Garey, 2009). These training sessions allow adequate time to review scenarios in detail, and trainees are given the opportunity to prepare and operate the equipment and practice procedures on an individualized basis. Others have used simulators to provide additional resuscitation training (Halamek, 2008). All of these training elements help prepare teams for future resuscitations.

The process of neonatal resuscitation requires that the medical team make rapid medical decisions to effectively transition a newborn from fetal to neonatal life. If the possible need for resuscitation is anticipated, the use of checklists can help the care team prepare for the specific circumstances of the particular delivery, familiarize themselves with other team members and the team leader, reinforce appropriate communication, ensure that the necessary equipment is available for prompt initiation of support critical to a successful neonatal resuscitation, and encourage a debrief to determine if further improvements are necessary for this process. The use of checklists in neonatal resuscitation would therefore seem logical. Checklists have been used in the aviation industry for many years to reduce errors and improve safety of passengers. In the last several years, these tools have begun to be embraced by the medical community to improve patient safety and patient care. They have been found to be useful in helping teams function more effectively, both in simulated environments and in clinical environments. While their use has been shown to yield low compliance when first introduced (Finer and Rich, 2010; Vats et al., 2010), the use of checklists has become a required standard for high-risk interventions such as emergency room traumas and surgical procedures and has been shown to reduce operative mortality (Haynes et al., 2009). Although the initial World Health Organization safe surgery checklist showed a reduction in surgical mortality, the implementation in routine practice in one study failed to show a benefit (Urbach et al., 2014). Some have suspected this is because the implementation of checklists requires some training and a culture of quality as necessary accompanying factors.

The most recent American Academy of Pediatrics NRP guidelines recommend the use of checklists for mock codes and related equipment but fall short of recommending them for use in actual resuscitations (NRP, 2016). The use of checklists with a debrief for actual resuscitations provides a mechanism for improving communication and recognizing and resolving problems and should be an essential component of neonatal resuscitation. The use of checklists during neonatal resuscitation is helpful in improving overall communication and allows rapid identification of issues that need to be addressed by institutional leaders (Katheria et al., 2013). We have shown that the introduction of such checklists for neonatal resuscitation has led to improved communication and better overall team function. An example of our institutional checklist is shown in Fig. 24.5. While there needs to be further evaluation of the utility and benefit of checklists for neonatal resuscitation, we encourage the use of institution-specific checklists for neonatal resuscitation teams. The ILCOR recommendations state: “A standardized checklist to ensure that all necessary supplies and equipment are present and functioning may be helpful...” When perinatal risk factors are identified, a team should be mobilized and a team leader should conduct a pre-resuscitation briefing, identify interventions that may be required, and assign roles and responsibilities to the team members. During resuscitation, it is vital that the team demonstrates effective communication and teamwork skills to help ensure quality and patient safety... It is still suggested that briefing and debriefing techniques be used whenever possible for neonatal resuscitation” (Perlman et al., 2015).

Transition and Resuscitation

After birth, blood flow in the umbilical arteries and vein usually continues for a few minutes. The additional blood volume transferred to the baby during this time is known as a placental transfusion. During the first 30 seconds of delayed cord clamping (DCC),

blood volume in the newborn increases by at least 12 mL/kg (Aladangady et al., 2006; Meyer and Mildenhall, 2012; Sommers et al., 2012; Takami et al., 2012; Katheria et al., 2014). The timing of umbilical cord clamping influences the amount of placental transfusion and subsequent plasma and red blood cell volume of the newborn (Yao et al., 1969; Yao and Lind, 1977). Early clamping may deprive newborns of blood that has an important role in opening the lungs (Jaykka, 1958), increasing cardiac output (Katheria et al., 2015), enhancing lung fluid clearance, and improving oxygen delivery to the newborn's tissues (Isobe et al., 2000; Jaiswal et al., 2015).

Recommendations and Evidence for Delayed Cord Clamping

The established practice of clamping the umbilical cord immediately after the delivery of the newborn was a result of the practice of limiting postpartum hemorrhage, which included immediate cord clamping. However, it was subsequently realized that immediate cord clamping was not required to reduce such hemorrhages. In fact there is no high-level trial-based evidence supporting the use of immediate cord clamping, and such immediate cord clamping has never been subjected to any controlled trial apart from its use as the control group in recent trials of other approaches to allow an adequate placental transfusion. The American College of Obstetricians and Gynecologists recommends a 30–60-second delay before the umbilical cord is clamped in all preterm deliveries, when feasible, to ensure that at-risk newborns receive an adequate placental transfusion (Raju, 2012). The timing for clamping of the umbilical cord after birth is a critical part of the resuscitation of preterm newborns and may have important benefits for perinatal outcomes. Some potential risks that have been raised with DCC, largely derived from term newborn studies, include increased rates of hyperbilirubinemia, polycythemia, and transient tachypnea in the newborn and increased risks of postpartum hemorrhage in the mother. However, several metaanalyses have demonstrated that there were no increases in these morbidities in preterm newborns (Rabe et al., 2012; Backes et al., 2014), and further, DCC does not increase maternal hemorrhage or blood loss (Eichenbaum-Pikser and Zasloff, 2009). In addition, these metaanalyses demonstrated that providing additional placental blood by either DCC or cord milking was associated with less need for transfusion, better circulatory stability, less intraventricular hemorrhage (all grades), decreased mortality, and lower risk of necrotizing enterocolitis (Rabe et al., 2012; Backes et al., 2014). The evidence to date shows that DCC substantively increases hemoglobin and iron stores in early infancy (Andersson et al., 2011). Inadequate iron stores in infancy may have an irreversible impact on the developing brain despite oral iron supplementation. Iron deficiency in infancy can lead to neurologic issues in older children, including poor school performance, decreased cognitive abilities, and behavioral problems. (Mercer and Erickson-Owens, 2012). Andersson et al. (2015) demonstrated that DCC increased scores in the fine-motor and social domains at 4 years of age, particularly in boys.

Cord Milking

Cord milking is an alternative to DCC that is used when the cord must be cut immediately for medical reasons, often because the newborn is in need of immediate resuscitation as judged by the clinician overseeing the resuscitation. Cord milking consists of encircling the umbilical cord with the thumb and forefingers,

gently squeezing a short segment of the cord, and slowly pushing the blood through the cord to the newborn's abdomen three to four times.

For newborns born by cesarean there has been a concern that DCC may not provide an adequate placental transfusion. Aladangady et al. (2006) reported lower circulating red cell volume with DCC in newborns born by cesarean compared with vaginal delivery. They also found the duration of delay, up to 90 seconds, increased blood volume in neonates born by vaginal delivery but not cesarean delivery. For neonates born by cesarean, cord milking appears to offer benefits over DCC for 45–60 seconds. Compared with DCC,

cord milking results in greater blood flow to and from the heart, higher hemoglobin levels, and higher blood pressure in neonates born by cesarean (Katheria et al., 2015). Among a smaller number of vaginal births, there was no difference in blood volume between newborns undergoing cord milking and those undergoing DCC.

Breathing During Delayed Cord Clamping

Animal studies and one epidemiologic study suggest cord clamping should not occur until the newborn is breathing (Bhatt et al., 2013; Ersdal et al., 2014). One clinical study suggested that DCC

results in an inadequate transfusion in depressed newborns who are not breathing during the delay (Nevill and Meyer, 2015). It compared nonbreathing newborns with breathing newborns who underwent DCC and found that nonbreathing newborns had a lower 1-minute Apgar score, were more likely to be intubated, and were at greater risk of chronic lung disease or severe intraventricular hemorrhage (Nevill and Meyer, 2015). However, it is unclear in preterm newborns whether a few gasping breaths or positive pressure ventilation (PPV) is required. Most newborns will tolerate 60 seconds of delay without obvious deterioration. We need more observational data to characterize the need for resuscitation during this critical interval. While hypotonia and pallor may be relevant, most newborns will improve during DCC, and few if any studies have used oximetry during DCC to determine actionable levels. Our own study (Neonatal Resuscitation with Intact Cord, $n = 150$), where newborns were randomized to undergo DCC alone or receive ventilation during DCC (ClinicalTrials.gov identifier NCT02231411; Katheria et al., 2017), found that ventilation during DCC was feasible but did not lead to any improvements immediately after delivery or reduce neonatal morbidity when compared with simple stimulation during DCC. Our study suggests that more than 90% of preterm newborns will initiate spontaneous breathing during DCC if given some form of stimulation. Thus stimulation to encourage breathing may be as effective as attempting to establish ventilation during DCC in premature newborns. While organizations such as the World Health Organization (2012) have suggested that interventions such as PPV can be started during DCC, our study did not show a measurable benefit from starting interventions when compared with stimulation alone, and larger trials are needed in this area.

Clinical trials have demonstrated that both DCC and cord milking in preterm newborns increase cardiac output (Katheria et al., 2015), measures of systemic blood flow (Sommers et al., 2012), and brain oxygen extraction (Takami et al., 2012). Importantly, there is no high-level trial-based evidence supporting the use of immediate cord clamping, which has never been subjected to any controlled trial apart from its use as the control group in recent trials.

Providers currently need to evaluate the large body of evidence supporting early placental transfusions (from DCC or cord milking) and compare it with the lack of evidence supporting immediate cord clamping. Providing only warmth and stimulation during DCC may be as good as initiation of respiratory support during DCC, but more studies are needed. Further studies are also needed to determine the optimal type of placental transfusion, the optimal duration of delay, and the use of supportive respiratory interventions; many such studies are ongoing. In the interim, the best available evidence to date along with policy statements from national organizations suggests that DCC should be the standard of care for preterm newborns who do not require resuscitation, and cord milking should be reserved for cases when DCC cannot be performed (Perlman et al., 2015).

Delivery Room Monitoring

Assessment

Immediately after birth the newborn's condition is evaluated by general observation as well as measurement of specific parameters. Typically a healthy newborn will cry vigorously and maintain adequate respirations. The color will transition from blue to pink in the first 2–5 minutes, the heart rate will remain in the region

of 140–160 beats per minute (bpm), and the newborn will demonstrate adequate muscle tone with some flexion of the extremities. The overall assessment of a newborn who is having difficulty with the transition to extrauterine life will often reveal apnea, bradycardia, hypotonia, and cyanosis or pallor.

Following the initial steps of resuscitation, interventions are based mainly on the evaluation of respiratory effort and heart rate, so both must be continually assessed throughout the resuscitation.

Heart Rate

Previous NRP recommendations only required a snapshot of the heart rate every 30 seconds to determine whether it fell between two critical cut points (60 and 100 bpm) as defined in the guidelines. Even if the heart rate is being auscultated and manually tapped out by hand, it can be difficult for the leader of the resuscitation to recognize changes quickly. With the inclusion of pulse oximetry for high-risk deliveries, all resuscitation teams can now monitor the heart rate continuously as long as the oximeter is functioning (Kattwinkel et al., 2010). However, the pulse oximeter, while helpful, does not provide a reliable heart rate in the first few minutes of life. Importantly, this is a critical period when decisions, such as the need to begin PPV, must be made. Our group demonstrated that the median time to obtain the heart rate of very low birth weight newborns (<1500 g), by means of oximetry, was 67 seconds (interquartile range 50–93 seconds) (Gandhi et al., 2013).

ECG, which derives from the electrical activity of the heart, is not dependent on the circulation and so is less affected by the transitional state of the newborn. In trials comparing oximetry with ECG, early application of ECG electrodes during newborn resuscitation can provide the resuscitation team with a continuous reliable audible heart rate earlier, and its use may improve the timeliness of appropriate critical interventions when compared with pulse oximetry alone (Katheria et al., 2012; Mizumoto et al., 2012). In addition, heart rate measured by ECG has been found to be higher than that measured by oximetry particularly early in resuscitation when low signal messages occur (Narayan et al., 2015). The seventh edition of the NRP textbook suggests the use of ECG to provide a rapid and accurate estimation of heart rate (Perlman et al., 2015; NRP, 2016).

Airway Pressure

Managing ventilation in the transitioning newborn may be one of the most difficult procedures faced by the resuscitation team. Positive end-expiratory pressure (PEEP) is used during resuscitation of preterm newborns to assist in establishing and maintaining FRC in the surfactant-deficient lung. It is difficult to recognize subtle changes in PEEP with a manometer. Real-time tracings of airway pressure allow the recognition of patterns, such as slow rises or falls in PEEP. When a T-piece resuscitation device is used, the airway pressure plot also provides the team with a visual cue of mask leak during ventilation, as the inspired airway pressure changes from consistent and flat to variable and curvy.

Mechanical ventilation in preterm newborns has been moving in the direction of “gentler ventilation” for years. This means low mean airway pressures and low ventilation rates. In the delivery room, where devices that regulate respiratory support are not generally present, ventilation rates and mean airway pressures can quickly be increased to levels reserved for much sicker newborns in the NICU. The visual display of the airway pressure waveform, along with digital readouts of mean airway pressure and respiratory

• **Fig. 24.6** Complete Airway Occlusion During Mask Positive Pressure Ventilation in an Extremely Low Birth Weight Newborn. Adequate positive pressure ventilation is provided, and suddenly the inflation and expiratory flow curves both display fewer flow movements and no tidal volume, and reducing expiratory CO_2 is displayed. The peak inspiratory pressure and positive end-expiratory pressure are maintained during positive pressure ventilation. ETCO_2 , end-tidal carbon dioxide; PEEP , positive end-expiratory pressure; PPV , positive pressure ventilation. (Courtesy of G. Schmolzer.)

rate, can quickly alert the team with feedback that excessive pressure is being provided to the newborn. However, the main issue with airway pressure monitoring is that achievement of a target pressure does not ensure that the newborn has received an adequate breath because of possible airway obstruction or leak (Finer et al., 2009). Therefore additional tools to measure tidal volumes, determine airway patency, and detect carbon dioxide (CO_2) are required.

Tidal volume can now be monitored with respiratory function monitors (RFMs) that are placed in the respiratory circuit (Schmolzer et al., 2010). Monitoring of tidal volume is standard on any current neonatal ventilator, but measuring spontaneous tidal volume, either in the NICU or in the delivery room, can be difficult. RFMs, which record airflow, airway pressure, and tidal volume, have been shown to be an effective tool in providing feedback to users in the delivery room (Schmolzer et al., 2012). In addition, it has been suggested that respiratory function monitoring should be used to measure tidal volumes to avoid harming the lungs (Schmolzer et al., 2008). The use of RFMs has been shown to

reduce mask leak, increase mask adjustments, and lower the rate of excessive tidal volumes. RFMs can display airway obstruction by reduction in both the expiratory gas flow and the inspiratory gas flow and no tidal volume (Fig. 24.6). Trials are needed to determine whether the RFM in the delivery room reduces neonatal morbidity.

The use of a colorimetric CO_2 detector during hand ventilation provides confirmation that gas exchange is occurring by the observed color change of the device, alerting the operator to an obstructed airway with lack of such color change (Leone et al., 2006). Airway obstruction is very common in the preterm newborn during PPV immediately after birth (Finer et al., 2009; Schmolzer et al., 2011). The site of obstruction may be laryngeal or supralaryngeal. It is important to remember that these CO_2 detectors will not change color in the absence of pulmonary blood flow, as occurs with inadequate cardiac output. One should be aware, however, that such colorimetric detectors can increase the overall resistance of commonly used resuscitation devices, including T-pieces, bags,

and masks. At times, multiple maneuvers are required to achieve an open airway, such as readjusting the head and mask positions, choosing a mask of more appropriate size, and further suctioning of the pharynx.

Our recommendation for most neonatal centers includes the use of ECG for early heart rate assessment, now referred to in the 2016 NRP recommendations, early use of pulse oximetry, and the use of a colorimetric CO₂ detector (also discussed in the 2016 NRP guidelines), which would provide adequate delivery room monitoring for resuscitation of newborns. RFMs providing real-time tidal volume and airway leak are ideally suited for academic centers focusing on neonatal resuscitation research.

Initial Steps: Temperature Management and Maintaining the Airway

In the first few seconds after birth all newborns are evaluated for signs of life, and a determination of the need for further assistance is made. This is done both formally as described in the NRP guidelines and informally as the initial care providers observe the newborn in the first few moments after birth. When the determination that further assistance and formal resuscitation are necessary, the newborn is placed on a radiant warmer and positioned appropriately for resuscitation to proceed. Appropriate positioning includes placing the newborn supine on the warmer in such a way that care providers have easy access. In addition, the head should be in a neutral or “sniffing” position to facilitate maintenance of an open airway. Frequently the oropharynx contains fluid that can be removed by suctioning with a standard bulb syringe.

A neonate born through meconium-stained amniotic fluid is at risk of aspirating meconium and developing significant pulmonary disease, known as meconium aspiration syndrome, which may also be accompanied by persistent pulmonary hypertension. For many years routine management of all newborns with meconium-stained amniotic fluid included suctioning of the mouth and pharynx once the head had been delivered but before the shoulders were delivered and endotracheal intubation and tracheal suctioning in an attempt to remove any meconium from the trachea and prevent the development of meconium aspiration syndrome. Routine suctioning of the mouth and nose before delivery of the shoulders has since been shown to be of no benefit in decreasing the incidence of meconium aspiration syndrome, the need for assisted ventilation, or mortality (Vain et al., 2004). Recognizing that intubation may not be necessary and may be associated with complications (Wiswell et al., 2000), the NRP recently stated that there was insufficient evidence to recommend routine suctioning of meconium in *nonvigorous* neonates born through meconium-stained amniotic fluid (NRP, 2016). The concern for routine suctioning of nonvigorous newborns is that it is more likely to result in delays in initiating ventilation, especially during difficult intubations or multiple attempts. The emphasis should be on initiating ventilation within the first minute after delivery in nonbreathing or ineffectively breathing newborns.

While temperature control is important for all newborns, it is particularly important for the extremely preterm newborn. Preterm newborns are commonly admitted to the NICU with core temperatures well below 37°C, and in a population-based analysis of all newborns of less than 26 weeks' gestation, more than one-third of them had an admission temperature below 35°C (Costeloe et al., 2000). More disturbing is the fact that these newborns with hypothermia on admission survived less often than those with

admission temperatures above 35°C. Admission temperatures can be increased in preterm newborns by immediate covering of the newborn's body with polyethylene wrap before the newborn is dried (Vohra et al., 2004). With this approach the newborn's head is left out of the wrap and is dried, but the body is not dried before wrap application. Other measures for maintaining newborn temperatures include performing resuscitations in a room that is kept at an ambient temperature of approximately 27°C–30°C, the use of radiant warmers with servo-controlled temperature probes placed on the newborn within minutes of delivery, and the use of an accessory prewarmed mattress or heating pads for the tiniest newborns. While hats are routinely used as a method of decreasing heat loss, they have not been shown to be consistently effective (McCall et al., 2008). It is important to note that as a required safety feature, radiant warmers substantially decrease their power output after 15 minutes of continuous operation in full-power mode. If this decrease in power is unrecognized, the newborn will be exposed to much less radiant heat. By application of the temperature probe and use of the warmer in servo-controlled mode, the temperature output will adjust as needed, and the power will not automatically decrease. The NRP has recently recommended that the temperature of newly born nonasphyxiated neonates be maintained between 36.5°C and 37.5°C after birth through admission and stabilization (NRP, 2016).

Assisting Ventilation

As the newborn begins breathing and replaces the lung fluid with air, the lung becomes inflated and an FRC is developed and maintained. With inadequate establishment of FRC, the newborn will not be adequately oxygenated and if this is prolonged will develop bradycardia. The provision of assisted ventilation when the newborn's spontaneous breathing is inadequate is probably the most important step in newborn resuscitation. The indications for providing assisted ventilation (PPV) include apnea or bradycardia (heart rate less than 100 bpm). PPV can be delivered noninvasively with a pressure delivery device and a face mask or a laryngeal mask airway (LMA) or delivered invasively with the same pressure delivery device and an endotracheal tube. Pressure delivery devices can include self-inflating bags, flow-inflating or anesthesia bags, and T-piece resuscitators, each with its advantages and disadvantages. The self-inflating bag is easy to use for inexperienced personnel and will work in the absence of a gas source. However, the self-inflating bag requires a reservoir to provide nearly 100% oxygen and does not consistently provide adequate PEEP. These devices may deliver very high pressure if not used carefully. Although they have pressure blow-off valves, these valves do not always open at the target blow-off pressures (Finer et al., 1986). An anesthesia bag or flow-inflating bag requires a gas source for use and allows the operator to vary delivery pressures continuously on the basis of the compliance felt but requires significant practice to develop expertise. However, using a test lung and intermittent airway occlusion, even experienced anesthesiologists were unable to recognize the increased resistance from an airway obstruction using only their hands (Spears et al., 1991). A T-piece resuscitator is easy to use, requires a gas source, and delivers the most consistent levels of pressure but requires intentional effort to vary pressures (Hoskyns et al., 1987). The flow-inflating bag and T-piece resuscitator allow the operator to deliver continuous positive airway pressure (CPAP) or PEEP relatively easily (Finer et al., 2001; Bennett et al., 2005).

A level of experience is required to perform assisted ventilation with a face mask and resuscitation device, and this is especially

true for an extremely low birth weight newborn. It is important to maintain an open airway for pressure to be transmitted to the lungs. The procedure for obtaining and maintaining an open airway includes, at minimum, clearing of fluid with a suction device, holding the head in a neutral position, and sometimes lifting the jaw slightly anteriorly. The face mask must make an adequate seal with the face for air to pass to the lungs effectively. No device will adequately inflate the lungs if there is a large leak between the mask and the face. Wood et al. (2008) measured face mask leaks of more than 55% when participants were evaluated providing positive pressure to manikins without instruction. The amount of leakage was decreased to approximately 30% with specific instruction. Until recently there were no masks that were small enough to provide an adequate seal over the mouth and nose for the tiniest newborns. Such masks are now readily available and facilitate bag-and-mask resuscitation of very small newborns. Signs that the airway is open and air is being delivered to the lungs include visual inspection of chest rise with each breath and, more importantly, improvement in the clinical condition, including heart rate and color.

We recommend that the resuscitation team attempt to achieve the target inspiratory pressures as the first goal in providing bag-and-mask resuscitation. Failure to achieve such pressures usually indicates a significant leak, which should be addressed by the repositioning of the mask and jaw or selection of a better-fitting mask. Once the target pressure has been achieved, the colorimetric detector is useful in determining whether there is airway obstruction, and failure to achieve an adequate color change in the face of delivering targeted pressures requires further attention to the airway, including repositioning, suctioning, and use of higher airway pressures. The seventh edition of the NRP textbook states that a colorimetric CO₂ detector can be used during ventilation corrective steps (NRP, 2016). Alternative methods of providing an open airway include the use of a nasopharyngeal tube (Lindner et al., 1999) or an LMA device (Grein and Weiner, 2005). Failure of these interventions requires immediate intubation. Prolonged attempts at ventilation against an unrecognized obstructed airway could result in further, more aggressive and hazardous procedures, such as chest compressions and/or medication administration.

The amount of pressure provided with each breath during assisted ventilation is critical to the establishment of lung inflation and therefore adequate oxygenation. Although it is important to provide adequate pressure for ventilation, excessive pressure can contribute to lung injury. Achieving the correct balance of these goals is not simple and is an area of resuscitation that requires more study. A single specific level of inspiratory pressure will never be appropriate for every baby. Initial inflation pressures of 25–30 cmH₂O are probably adequate for most term babies. The current NRP textbook recommends initial pressures of 20–25 cmH₂O for preterm newborns. The first few breaths may require increased pressure if lung fluid has not been cleared, as occurs when the newborn does not initiate spontaneous breathing. Newborns with specific pulmonary disorders such as pneumonia or pulmonary hypoplasia also frequently require increased inspiratory pressure. It has been shown that use of enough pressure to produce a visible chest rise is associated with hypocarbia on admission blood gas evaluation (Tracy et al., 2004), and excessive pressure may decrease the effectiveness of surfactant therapy (Bjorklund et al., 1997). It may be possible to establish FRC without increasing peak inspiratory pressures by providing a few prolonged inflations (inspiration for 3–5 seconds) although the use of prolonged inflations has not been associated with better outcomes than conventional breaths

during resuscitation (Lindner et al., 2005). Choosing the actual initial inspiratory pressure is less important than continuously assessing the progress of the intervention. A manometer in the circuit during assisted ventilation provides the clinician with an indication of the administered pressure, although if the airway is blocked this pressure is not delivered to the lungs. The volume of air delivered to the lungs seems to be more important than the absolute pressure delivered in the development of lung injury.

The most critical component of continued assessment is evaluation of the newborn's response to the intervention. If after ventilation has been initiated the condition of the newborn does not improve, then the ventilation is most likely inadequate. In our experience the two most likely reasons for inadequate ventilation are a blocked airway and insufficient inspiratory pressure. The occluded airway can be noted with use of a colorimetric CO₂ device as described earlier and frequently can be corrected with changes in position or suctioning, while inadequate pressure is corrected by adjustment of the ventilating device.

Use of continuous pressure throughout the breathing cycle seems to be beneficial for the establishment of FRC and improvement in surfactant function (Michna et al., 1999; Hartog et al., 2000; Siew et al., 2009). This is accomplished during assisted ventilation with the use of PEEP or with CPAP when additional inspiratory pressure is not needed. In the absence of PEEP, a lung that has been inflated with assisted inspiratory pressure will lose on expiration most of the volume that had been delivered on inspiration. This pattern of repeated inflation and deflation is frequently thought to be associated with lung injury. In preterm newborns a general approach of using CPAP as a primary mode of respiratory support in NICUs has been associated with a low incidence of chronic lung disease (Avery et al., 1987; Van Marter et al., 2000; Ammari et al., 2005; Vanpee et al., 2007). te Pas and Walther (2007) evaluated a ventilation strategy that included use of a T-piece resuscitator and a nasopharyngeal tube to deliver a prolonged breath followed by CPAP, compared with use of a self-inflating bag to deliver PPV when needed without any CPAP provided, until newborns reached the NICU. Newborns treated with the prolonged breath and CPAP required less endotracheal intubation and had lower rates of bronchopulmonary dysplasia. More recently, this same group demonstrated that probably because of airway obstruction at or above the larynx, they could not deliver a sustained inflation to premature newborns who were apneic (van Vonderen et al., 2014).

The use of CPAP compared with endotracheal intubation and mechanical ventilation as the initial mode of respiratory support was evaluated in the Continuous Positive Airway Pressure or Intubation at Birth (COIN) trial (gestational age [GA] 25–28 6/7 weeks) (Morley et al., 2008), but the intervention did not begin until 5 minutes after delivery and can therefore not inform the decision about use of these therapies as immediate resuscitative interventions. The Surfactant, Positive Pressure, and Oxygenation Randomized Trial (SUPPORT) (GA 24–27 6/7 weeks) demonstrated that the use of early CPAP can be an effective alternative to intubation and surfactant as the primary mode of respiratory support in preterm newborns (Finer et al., 2010). While these trials did not evaluate these therapies specifically in the resuscitation period, the respiratory support provided shortly after birth should probably mimic the support provided in the NICU following delivery.

If assisted ventilation is necessary for a prolonged period or if other resuscitative measures have been unsuccessful, ventilation must be provided by a securer device such as an endotracheal tube.

• **Fig. 24.7** View of the Glottis and Vocal Cords as the Laryngoscope Is Gently Lifted. (From Kattwinkel J, ed. *Neonatal Resuscitation Textbook*. 5th ed. Elk Grove Village: American Heart Association and American Academy of Pediatrics; 2006.)

If it has been difficult to maintain an open airway while ventilation has been given via a face mask, the appropriately placed endotracheal tube will provide a stable airway. This will allow more consistent delivery of gas to the lungs and therefore provide the ability to establish and maintain FRC. Currently in the United States, intubation with an endotracheal tube is required for administration of surfactant and may be used to administer other medications, such as epinephrine, if necessary for resuscitation. The intubation procedure is often critical for successful resuscitation, requires a significant amount of skill and experience to perform reliably, and may be associated with serious complications. The placement of a laryngoscope in the pharynx often produces vagal nerve stimulation that leads to bradycardia. A photograph of the desired view of the larynx is presented in Fig. 24.7. Assisted ventilation must be paused for the procedure, which if prolonged can lead to hypoxemia and bradycardia. Intubation has been shown to increase blood pressure and intracranial pressure (Kelly and Finer, 1984). Trauma to the mouth, to the pharynx, to the vocal cords, and to the trachea is a possible complication of intubation. If the intubation procedure is performed when the newborn already has bradycardia and hypoxemia, this can lead to a further decline in heart rate and oxygenation (O'Donnell et al., 2006). Additionally, hypoxia and bradycardia are more likely when intubation attempts are prolonged beyond 30 seconds. Therefore it is most appropriate to attempt to stabilize the newborn with noninvasive ventilation before the procedure is performed and to limit each attempt to 30 seconds or less (Lane et al., 2004) and allow time for the newborn to recover with noninvasive ventilation between attempts. If misplacement of the endotracheal tube in the esophagus goes unrecognized, the newborn may experience further clinical deterioration. Clinical signs that the endotracheal tube has been correctly placed in the trachea include auscultation of breath sounds over the anterolateral aspects of the lungs (near the axilla), mist visible in the endotracheal tube, chest rise, and clinical increase in heart rate and improvement in color or increase in oxygen saturation. The use of a colorimetric CO₂ detector to confirm intubation significantly decreases the amount of time necessary to determine correct placement of the endotracheal tube from approximately 40 seconds to less than 10 seconds (Aziz et al., 1999; Repetto et al., 2001). We consider this to be the primary method of determining endotracheal tube placement.

Successful placement of the endotracheal tube is not always easy and is sometimes not possible. Airway anomalies may make alternative methods of airway management necessary. An LMA is one such alternative that has been described for use in patients with Pierre Robin sequence or other airway anomalies (Yao et al., 2004). Some practitioners have reported using the LMA for all positive pressure delivery after birth, with success noted in newborns as small as 1000 g (Gandini and Brimacombe, 1999). Administration of medications, including surfactant and epinephrine, through this device has undergone preliminary investigation (Trevisanuto et al., 2005; Chen et al., 2008). The most recent comparison of the use of an LMA versus mask resuscitation demonstrated better outcomes for newborns weighing 1500 g or more at birth with the LMA, and we advise that a small LMA should always be available in the resuscitation area.

Transitional Oxygenation and Oxygen Use

It is critical to remember that fetal arterial oxygen levels are much lower than newborn arterial oxygen levels. The transition from fetal to newborn levels does not happen instantaneously. Using pulse oximetry in the immediate newborn period, several investigators have established that this transition with an ultimate oxygen saturation level of more than 90% takes 5–15 minutes to occur in newborns who do not otherwise require resuscitation. For term and preterm nonresuscitated newborns the median oxygen saturation at 3 minutes was 76% (interquartile range 64%–87%) and at 5 minutes was 90% (interquartile range 79%–91%) (Kamlin et al., 2006). The expected oxygen saturation levels are slightly lower for preterm neonates compared with term neonates and for neonates delivered via cesarean compared with those delivered vaginally (Rabi et al., 2006). Oxygen saturation levels measured in preductal sites are 5%–10% higher than those measured from postductal sites for approximately 15 minutes of life (Mariani et al., 2007). A great deal of variability occurs in the saturation values among different well individuals during the first 5 minutes of life, but a resuscitation team can expect there to be a steady, albeit slow, increase in levels over several minutes. If the values are below a threshold at different time points or not progressively increasing, intervention should be considered.

The use of pure oxygen for ventilation became routine practice in resuscitation simply because it seemed logical that oxygen would be beneficial. However, the recognition that oxygen could also be toxic led some investigators to question this previously well-accepted practice. The toxicity of oxygen is anticipated when the cellular antioxidant capacity is impaired as occurs during the reperfusion phase following an hypoxic–ischemic insult. After animal studies showed the potential harmful effects of oxygen (Rootwelt et al., 1992; Poulsen et al., 1993), clinical trials were conducted to evaluate the effects of supplemental oxygen use during resuscitation of depressed newborns. Several worldwide trials have compared the use of pure (100%) oxygen with room (ambient) air (21% oxygen) as the initial ventilating gas for primarily term asphyxiated newborns. These trials found that air was as successful as oxygen in achieving resuscitation, and newborns resuscitated with air had a shorter time to initiate spontaneous breathing and less evidence of oxidative stress (Saugstad et al., 1998; Vento et al., 2001; Ramji et al., 2003; Vento et al., 2003). Metaanalyses of trials demonstrated that newborns resuscitated with air had a lower risk of death than those resuscitated with pure oxygen (Tan et al., 2005; Rabi et al., 2007). These trials have been criticized because they were not all strictly randomized, and some sites were in developing countries. However,

metaanalysis of the strictly randomized trials that were mostly carried out in European centers demonstrates significant benefit for survival with the use of air as compared with pure oxygen (Saugstad et al., 2008).

The preterm newborn may be more susceptible to any harmful effects of excessive oxygen exposure because of decreased antioxidant enzyme capacity. Some of the newborns in the previous oxygen trials were preterm but a few weighed less than 1000 g. Review of the outcomes for preterm newborns (<37 weeks) demonstrated an even greater reduction in death for those initially resuscitated with room air compared with oxygen (Saugstad et al., 2005). NICUs generally attempt to reduce oxygen toxicity by limiting the amount of oxygen administered to newborns using an upper limit for oxygen saturation and adjusting supplemented oxygen levels to maintain saturation levels within that limit. The unlimited use of oxygen during resuscitation exposes the preterm newborn to higher oxygen saturation levels than would routinely be accepted in the NICU. Several small trials of oxygen use during resuscitation of preterm newborns have been performed in the last 3 years. Among 42 preterm neonates born at less than 32 weeks' gestation treated with either pure oxygen for 5 minutes or a targeted oxygen strategy beginning with 21% oxygen (Wang et al., 2008), those newborns initially given pure oxygen had higher peripheral arterial oxygen saturation (SpO_2) levels during the transition but did not have any differences in heart rate, need for intubation, or survival. The newborns provided with air from the start of resuscitation all required an increase in the amount of inspired oxygen to obtain the prespecified oxygen saturation targets. Using 30% versus 90% oxygen at the start of resuscitation and adjusting the concentration on the basis of the clinical status of the newborn, Escrig et al. (2008) found that newborns initially given 30% oxygen had lower overall exposure to oxygen without any adverse effects. The group initially given 30% oxygen received increased oxygen concentrations up to approximately 55% at 5 minutes, but both groups received similar oxygen concentrations after 4 minutes of life, with a level of approximately 35% by 15 minutes after delivery. In another study, these investigators reported a decrease in the incidence of bronchopulmonary dysplasia in newborns initially given 30% oxygen compared with 90% oxygen (Vento et al., 2009). The Room-Air Versus Oxygen Administration for Resuscitation of Preterm Infants (ROAR) study was a blinded, randomized controlled trial in 106 neonates born at 32 weeks' gestation or less comparing three oxygen strategies: one group received 100% oxygen throughout, one received 100% oxygen initially, and the third received 21% oxygen initially; in the last two groups the oxygen concentration was titrated to keep SpO_2 at 85%–92%. SpO_2 levels were below the prespecified target range 61% of the time in the group that received 21% oxygen initially and were above the target range 49% of the time in the group that received 100% oxygen throughout ($P < .001$) (Rabi et al., 2011). A recent retrospective study from the Canadian Neonatal Network demonstrated an increased risk of severe neurologic injury or death with resuscitation using room air (or room air with titrated increases to 40% oxygen) compared with 100% oxygen (Rabi et al., 2015).

The most recent large trial involving preterm newborns compared room air with 100% oxygen, the Targeted Oxygenation in the Resuscitation of Premature Infants and their Developmental Outcome (TO2RPIDO) study (ACTRN12610001059055), was stopped because of poor enrollment but also found increased mortality (<28 days) in neonates born at less than 28 weeks' gestation who were treated with low or titrated oxygen compared with

those who received 100% at the initiation of resuscitation (Vento et al., 2016).

An updated metaanalysis including these trials comparing initiation of resuscitation with high (>65%) or low (21%–30%) oxygen concentration no longer demonstrated any differences in survival (Oei et al., 2017) (Fig. 24.8). Larger trials such as the ongoing Premature Infants Resuscitated with Oxygen or Air (PRESOX) study (NCT01773746) and the planned TO2RPIDO trial involving preterm newborns treated with different oxygen strategies are necessary to determine the long-term effects of resuscitation with different oxygen concentrations. Oxygen use in the first few minutes of life could impact survival and common neonatal morbidities associated with prematurity and free-radical disease such as neurodevelopmental impairment, retinopathy of prematurity, bronchopulmonary dysplasia, and necrotizing enterocolitis.

The use of oxygen concentrations between 21% and 100% requires compressed air and a blender. Different organizations throughout the world have provided differing recommendations on the use of oxygen for newborn resuscitation. The NRP has recommended initiating resuscitation for term newborns with air when ventilation is needed (Perlman et al., 2010). For the preterm neonate born at less than 35 weeks' gestation, ILCOR recommended initiating resuscitation with a low oxygen concentration (21%–30%) and adjustment based on target oxygen saturations (1 minute 60%–65%, 2 minutes 65%–70%, 3 minutes 70%–75%, 4 minutes 75%–80%, 5 minutes 80%–85%, 10 minutes 85%–95%) (Perlman et al., 2015). Our approach has been to begin with 30% oxygen and adjust the concentration slowly, attempting to mimic the gradual transition in these SpO_2 values. Fig. 24.9 demonstrates continuous physiologic data during the first 10 minutes of life for a newborn resuscitated with this targeted oxygen strategy.

Assisting Circulation

In newborns the need for resuscitative measures beyond assisted ventilation is extremely rare. Additional circulatory assistance can include chest compressions, administration of epinephrine, and volume infusion. In a cohort study of neonates born at less than 32 weeks' gestation in Canadian NICUs, 5.2% of all neonates weighing less than 1000 g received chest compressions and/or epinephrine compared with 3.4% of neonates weighing more than 1000 g. (Soraisham et al., 2014). Ventilation remains the most critical priority in neonatal resuscitation. However, if adequate ventilation is provided for 30 seconds and bradycardia with a heart rate of less than 60 bpm persists, chest compressions are initiated. Further attention to ventilation with the use of increased pressures and/or intubation may be required. Chest compressions are preferably provided with two thumbs on the sternum while both hands encircle the chest (Menegazzi et al., 1993). The chest is then compressed in a 3:1 ratio coordinated with ventilation breaths.

Further circulatory support may be necessary if adequate chest compressions do not result in an increase in heart rate after 30 seconds. Epinephrine is then indicated as a vasoactive substance that increases blood pressure by α -receptor agonism, coronary perfusion pressure, and heart rate by β -receptor agonism. Intravenous (IV) administration of epinephrine is more likely to be effective than endotracheal administration. The IV dose of 0.01–0.03 mg/kg (0.1–0.3 mL/kg of a 1:10,000 solution) is currently recommended. Early placement of an umbilical venous catheter is critical to deliver epinephrine by IV quickly enough to be effective. To place an umbilical catheter as quickly as possible, it is necessary to have the equipment readily available and to begin

• **Fig. 24.8** Tracing of Physiologic Data During Transition. The pulse rate, oxygen saturation, and oxygen concentration measured within 30 seconds of birth are displayed here. The pulse oximeter is placed on the newborn's right hand as soon as possible. Point A shows when the pulse oximeter begins working. Point B shows the oxygen saturation (SpO_2) at 3 minutes (approximately 80%). This newborn was initially treated with 40% oxygen, and the concentration was adjusted to achieve SpO_2 of 85% to 90% by 5 minutes of life. When the oxygen is reduced to 21% at approximately 7.5 minutes of life, the SpO_2 decreases, and the oxygen concentration is increased again. *Bpm*, Beats per minute; *FiO₂*, oxygen concentration.

• **Fig. 24.9** Tracing of a Newborn Resuscitated With a Targeted Oxygen Saturation Strategy.

the procedure as soon as possible. This could be accomplished by the lead resuscitator assigning the task of placing the catheter as soon as chest compressions are initiated. If there is any prenatal indication that substantial resuscitation will be required, the necessary equipment for umbilical venous catheter placement should be prepared before delivery as completely as possible. Epinephrine may be given by an endotracheal tube but the efficacy of this delivery method is not as certain, and therefore an increased dose (0.03–0.1 mg/kg) is currently recommended. Epinephrine doses may be repeated every 3 minutes if heart rate does not increase. Excessive epinephrine may result in hypertension, which in preterm newborns may be a factor in the development of intraventricular hemorrhage. However, the risks are balanced by the benefit of successful resuscitation in a newborn who might not otherwise survive.

If the newborn has not responded to any of the prior measures, a trial of increasing intravascular volume should be considered by the administration of crystalloid or blood. Situations associated with fetal blood loss are also frequently associated with the need for resuscitation. These include placental abruption, cord prolapse, and fetal maternal transfusion. Some of these clinical circumstances will have an obvious history associated with blood loss, whereas others may not be readily evident at the time of birth. Signs of hypovolemia in the newborn are nonspecific but include pallor and weak pulses. Volume replacement requires IV access, for which emergent placement of an umbilical venous catheter is essential. Any newborn who has signs of hypovolemia and has not responded quickly to other resuscitative measures should have an umbilical venous line placed and a volume infusion administered. The most common (and currently recommended) fluid for volume replacement is isotonic saline. A trial volume of 10 mL/kg is given initially and repeated if necessary. If a substantial blood loss has occurred, the newborn may require infusion of red blood cells to provide adequate oxygen-carrying capacity. This can be accomplished emergently with noncrossmatched O-negative blood, with blood collected from the placenta, or with blood drawn from the mother, who will have an antibody profile compatible with her newborn at the time of birth. Because not all blood loss is obvious and resuscitation algorithms usually discuss volume replacement as the last resort of a difficult resuscitation, the clinician needs to keep a high index of suspicion for significant hypovolemia so that action may be taken to correct the problem as promptly as possible. Therefore in situations where the possibility of hypovolemia is known before birth, it would be wise to provide a placental transfusion, prepare an umbilical catheter, prepare an initial syringe of isotonic saline, and discuss with the blood bank and the delivering physicians the possibility that noncrossmatched blood may be required.

Apgar Score

The overall assessment of a newborn was quantified by the anesthesiologist Virginia Apgar in the 1950s with the Apgar score (Apgar, 1953). The score describes the newborn's condition at the time it is assigned and consists of a 10-point scale with a maximum of 2 points assigned for each of the following categories: respirations, heart rate, color, tone, and reflex irritability. Table 24.2 shows the detailed components of the score. While the components of the score include items that are assessed for determination of interventions, the score itself is not used to determine the need for interventions. The score was initially intended to provide a uniform, objective assessment of the newborn's condition and was used as a tool to compare different practices, especially obstetric anesthesia. Despite

TABLE 24.2 The Apgar Score

| Feature Evaluated | 0 Points | 1 Point | 2 Points |
|------------------------|------------|---|---------------------|
| Heart rate (beats/min) | 0 | <100 | >100 |
| Respiratory effort | Apnea | Irregular, shallow, or gasping respirations | Vigorous and crying |
| Color | Pale, blue | Pale or blue extremities | Pink |
| Muscle tone | Absent | Weak, passive tone | Active movement |
| Reflex irritability | Absent | Grimace | Active avoidance |

the intent of objectivity, there is often disagreement in score assignment among various practitioners (O'Donnell et al., 2006). Low scores are associated with increased risk of neonatal death (Casey et al., 2001) but have not been predictive of neurodevelopmental outcome (Nelson and Ellenberg, 1981). Interpreting the score when interventions are being provided may be difficult, and current recommendations suggest that clinicians should document the interventions used at the time the score is assigned (American Academy of Pediatrics, 2006).

Specific Problems Encountered During Resuscitation

Neonatal Response to Maternal Anesthesia/Analgesia

Medications administered to the mother during labor can affect the fetus by transfer across the placenta and direct action on the fetus or by adversely affecting the mother's condition and therefore altering uteroplacental circulation and fetal oxygen delivery. The most commonly discussed complication of intrapartum medication exposure is perinatal respiratory depression after maternal opiate administration. The fetus can develop respiratory depression from the direct effect of the drug. Naloxone has been used during neonatal resuscitation as an opiate receptor antagonist to reverse the effects of fetal opiate exposure. Newborns of mothers who have long-term opiate exposure can potentially have a sudden withdrawal syndrome, including seizures, if they receive a narcotic antagonist. It is also critical that assisted ventilation be provided as long as spontaneous respirations are inadequate. ILCOR does not recommend naloxone as part of the initial resuscitation for newborns with respiratory depression in the delivery room (Perleman et al., 2010). The administration of a narcotic antagonist is never an acutely required intervention during neonatal resuscitation as such newborns can and should be treated with assisted ventilation.

The Use of Early Caffeine

Respiratory distress syndrome can be successfully treated in very preterm newborns with nasal CPAP beginning at birth. However, CPAP treatment will fail in many of these newborns, and they will require endotracheal intubation and surfactant administration

to achieve adequate gas exchange (Morley et al., 2008; Finer et al., 2010). Caffeine therapy given during the first 10 days after birth reduced the need for positive airway pressure by 1 week compared with placebo (Schmidt et al., 2006). Very early use of caffeine (immediately after birth) as a respiratory stimulant represents a potential adjunctive therapy with CPAP to prevent intubation. Recently, some European centers have adopted a technique to administer surfactant via a thin flexible catheter during spontaneous breathing while nasal CPAP is being received (minimally invasive surfactant therapy) (Kribs et al., 2008). As part of this protocol, newborns are given IV caffeine in the first hour after delivery. Caffeine's favorable efficacy and safety record in the NICU for the treatment of apnea of prematurity, and for preventing failed extubation, is well known (Erenberg et al., 2000; Schmidt et al., 2006; Schmidt et al., 2007; Henderson-Smart and Davis, 2010). A potential new direction for caffeine therapy targets early administration for preterm neonates at risk of respiratory failure and cardiovascular insufficiency (Lodha et al., 2015). Such an intervention should be feasible in most settings as IV access is routinely achieved in these patients for provision of IV fluids and antibiotics. Newborns treated initially with CPAP alone may take time to develop respiratory insufficiency and apnea. Waiting to give caffeine when these symptoms develop may not prevent the need for intubation. In a feasibility study of very early caffeine use, we found that very preterm newborns receiving caffeine in the first 2 hours of life had increased systemic blood flow and blood pressure compared with newborns who received caffeine at 12 hours after delivery (Katheria et al., 2015). Larger prospective studies are needed to determine the effects of early caffeine use on the need for intubation, intraventricular hemorrhage, and related long-term outcomes such as chronic lung disease and neurodevelopmental impairment.

Conditions Complicating Resuscitation

When resuscitation has proceeded through the steps described without improvement in the newborn's clinical condition, other problems should be considered. Some of these problems may be modifiable with interventions that could improve the course of the resuscitation. For example, an unrecognized pneumothorax could prevent adequate pulmonary inflation and if under tension could impair cardiac function. If the pneumothorax is recognized and drained, both gas exchange and circulation can be improved. Some congenital anomalies that were not diagnosed antenatally make resuscitation more difficult. Congenital diaphragmatic hernia is one such anomaly that is difficult to recognize on initial inspection of the newborn but can cause significant problems with resuscitation. The abdominal organs are displaced into one hemithorax, and the lungs are unable to develop normally. This may cause ventilation to be quite difficult. If the intestines are displaced into the thorax and mask ventilation is provided, the intestines will become inflated, making ventilation even more difficult. If the congenital diaphragmatic hernia is known before delivery or a presumptive diagnosis is made in the delivery room, the baby should be intubated early to prevent intestinal inflation. An orogastric suction tube should also be placed to decompress the inflated intestines.

Many other congenital anomalies that can lead to a difficult resuscitation will be more visibly obvious when the baby is born. For example, hydrops fetalis occurring for any reason can be associated with very difficult resuscitation. Although most cases are diagnosed on fetal ultrasonography before delivery, severe hydrops would be clearly visible on examination because of

significant skin edema and abdominal distention. Frequently peritoneal and/or pleural fluid will need to be drained to achieve adequate ventilation. Abdominal wall defects such as gastroschisis require special attention in the delivery room to ensure that the exposed bowel is covered in plastic to prevent excessive fluid loss and is protected from twisting or trauma. An orogastric suction tube is also important to decompress the stomach and limit chances of further vomiting. If assisted ventilation is necessary, early intubation as opposed to mask ventilation should be considered to prevent gastric distention. Newborns with neural tube defects should also have any exposed tissues protected with a sterile covering. Additionally, all efforts should be made to avoid pressure on the defect.

A situation that may create a particularly difficult resuscitation is a fetal congenital high airway obstruction. If a significant airway obstruction is diagnosed antenatally, an ex utero intrapartum treatment or EXIT procedure can be planned. This allows the establishment of a stable airway before the clamping of the umbilical cord that maintains placental function until the airway is secure. An airway obstruction may not necessarily be diagnosed before delivery and may create a very difficult resuscitation. The therapy will differ depending on the cause of the obstruction. An alternative airway (oral or nasopharyngeal) can be helpful if endotracheal intubation is not possible as can occur with severe micrognathia. Tracheal suctioning can be attempted if a tracheal plug is suspected. In extreme situations of airway obstruction, an emergency cricothyroidotomy may be attempted.

Birth trauma of any kind has been documented to occur in approximate 2.6% of all deliveries in the United States (Moczygemba et al., 2010). The most serious injuries are the variety of head injuries that can occur, including subgaleal hemorrhage and intracranial hemorrhage. Subgaleal hemorrhage is more often associated with vacuum-assisted delivery and is important to recognize because of the rapid blood loss that can occur into this soft tissue space. Intracranial hemorrhages such as subdural hematomas can occur, though many such injuries are mild and can be found incidentally after uncomplicated vaginal delivery. Spinal cord injuries after birth are extremely rare but can be quite severe with long-lasting functional limitations. Brachial plexus and other peripheral nerve injuries may be noticed in the delivery room and evaluated shortly after birth but should not interfere with the resuscitation efforts. Pressure injuries from forceps-assisted deliveries can be noted on examination and evaluated as necessary in accordance with the location of the injury. Fractures and lacerations may occur and need to be evaluated after the newborn has adequately transitioned.

Limits of Viability

Neonatal intensive care has increased survival at lower GAs, resulting in changes in the definition of viability over time. A variety of opinions regarding the lower limit of GA when intensive care should be offered exist among practitioners (Backes et al., 2015; Janvier and Lantos, 2016). The most recent edition of the NRP textbook states that if there is no chance for survival, such as birth at a confirmed GA of less than 22 weeks or severe congenital anomalies, resuscitation should not be offered (NRP, 2016). When the outcome is most uncertain, parents of the newborn are frequently included in the decision-making process. Making an informed decision about the provision of intensive care should be done with the best available information. One of the resources that is used to determine the likelihood of survival without severe disabilities has been provided by Tyson et al. (2008) using the Eunice Kennedy

Shriver National Institute of Child Health and Human Development Neonatal Research Network data. Using information regarding the GA, birth weight, sex, number of fetuses, and antenatal steroid exposure, one can calculate the risk of death and neurodevelopmental impairment. These predictive data, which were compiled from the participating centers of the Neonatal Research Network, a group of mostly academic centers, may currently be the best available national data for predicting outcome but do not necessarily represent the outcome at any single unit or of any individual baby. For mothers who present to a small inexperienced center with the possibility of delivery at a very preterm GA, every effort should be made to transport the mother to an experienced tertiary inborn center when possible.

Care After Resuscitation

Newborns who survive a significant resuscitation require special attention in the hours and days that follow. Frequent complications immediately following resuscitation include hypoglycemia, hypotension, and persistent metabolic acidosis. In addition term and near-term newborns with evidence of hypoxic–ischemic encephalopathy benefit from mild therapeutic hypothermia (Shankaran et al., 2005; Jacobs et al., 2007; Azzopardi et al., 2009). Mild therapeutic hypothermia in which the core body temperature is kept at 33.5°C has now been extensively evaluated and has been effective at reducing death or impairment in newborns with moderate to severe hypoxic–ischemic encephalopathy. The decreased temperature is thought to decrease the secondary injury that occurs after an hypoxic–ischemic insult. Hypothermia can be accomplished with both whole-body and head cooling, though clinical trials of whole-body cooling more effectively achieved a reduction in adverse outcome. The therapy is most beneficial when initiated as quickly as possible after an insult, with beneficial effects noted when treatment was initiated within 6 hours of birth. The timing of the insult in relation to the time of birth is not always obvious, making it difficult to know the actual timing of initiation of therapy after the insult. Mild hypothermia therapy should be considered when a newborn has required a significant resuscitation after birth, Apgar scores are low (especially 5-minute score <5), fetal or neonatal acidosis is documented on cord or newborn blood gases, and signs of encephalopathy are apparent. In addition, a history of a significant event likely to cause a hypoxic–ischemic insult should trigger a thorough evaluation of the newborn to determine whether hypothermia therapy is indicated. Hypothermia therapy is not currently available at all institutions. The seventh edition of the NRP textbook recommends therapeutic hypothermia should be considered for neonates born at term or near term with evolving moderate to severe hypoxic–ischemic encephalopathy, with protocol and follow-up coordinated through a regional perinatal system (NRP, 2016). However, all delivery services must be able to recognize the indications for therapy so that, if necessary, a transfer can be initiated as quickly as possible.

In neonates born without a heart rate or any respiratory effort, if resuscitation is performed to the full extent without any response, discontinuation is recommended after 10 minutes. From a review of 13 years of a data including 81,603 deliveries, Haddad et al. (2000) found that survival with an Apgar score of 0 at 1 minute occurred in 1.26 in 1000 delivered newborns without major malformations. Of 33 newborns with an Apgar score of 0 at both 1 and 5 minutes, 67% died before hospital discharge. A review of the available literature for newborns with an Apgar score of 0 at 10 minutes found that 94% of them either died or were severely

handicapped, while 3% were mild or moderately handicapped (Harrington et al., 2007).

The transition from fetal to neonatal life is a critical time in an individual's life and is an opportunity for care providers to have significant impact on the outcome of those newborns who need assistance. The need for newborn resuscitation, even when no signs of encephalopathy are recognized, increases the risk that children will have lower scores on IQ tests at school age (Odd et al., 2009). This is most likely because resuscitation is a marker for a prior insult. However, a well-performed resuscitation could be critical for a successful recovery. Neonatal care providers have an obligation to ensure that this process is performed as well as possible and that the resuscitation techniques are evaluated in an objective manner to promote continued improvement.

Newborn Evaluation

VALENCIA P. WALKER

KEY POINTS

- Detection of significant newborn problems in a timely fashion helps to prevent serious morbidities.
- A systematic approach to obtaining the prenatal and newborn history is essential.
- The initial newborn evaluation greatly informs the predischARGE evaluation and management plans.
- An appropriate level of vigilance is needed to detect the abnormal newborn “hiding” amid the healthy ones.
- An ongoing challenge of the newborn examination is the need to be efficient, thorough, and highly vigilant while simultaneously projecting an attitude of calming reassurance.
- The repetition of evaluating normal newborns and practicing calming reassurance should never promote complacency.

This chapter focuses on the medical evaluation of the apparently well newborn in the first few days after birth. As such, the emphasis will be on common problems, variations of normal and subtle abnormalities. Some clinical findings that suggest serious illness are also described but their inclusion is not intended to provide a complete differential diagnosis or guide to management. Physical findings pertinent to specific diseases and organ systems, evaluation of the dysmorphic newborn, and laboratory studies helpful in routine newborn care are described in greater detail in other chapters in this textbook.

Initial Newborn Evaluation: Key Elements

1. Obtain the history (prenatal, birth, family and social).
2. Perform a physical examination.
3. Evaluate and consider the impact of significant risk factors, history, and physical examination findings.
4. Determine the need for additional work-up and/or follow-up as indicated.
5. Provide education and counseling to parents/legal guardians. To complete these tasks requires skill and experience. For brevity, we refer to the person evaluating the newborn as a *pediatrician*. In some institutions the routine evaluation is performed by a general pediatrician, family practitioner, or pediatric nurse practitioner, and the neonatologist enters the well-baby nursery only as a consultant. In other institutions the neonatologist has direct responsibility for patients in the newborn nursery as well as in the neonatal intensive care unit (NICU). Regardless of which healthcare

professional is primarily responsible for the evaluation of newborns, this person should develop and maintain proficiency in the evaluation of the normal newborn, a task that requires its own particular set of skills.

In the normal nursery, the primary goal is to identify the small minority of babies with significant problems that may cause serious morbidity if not detected in a timely fashion. This includes the recognition of and consideration of the presence of psychosocial problems (e.g., maternal, family, and/or community) that may adversely impact both “normal” and “at risk” newborns. This goal must be accomplished with the understanding that the vast majority of babies encountered in the newborn nursery are completely healthy, despite wide variations in presentation and findings.

History

When obtaining the newborn’s history, the pediatrician may easily view himself/herself as an investigative reporter. Multiple sources of information are needed to complete the initial “fact gathering,” including:

1. The mother’s medical and obstetric history
2. The current pregnancy course
3. The social and family history (maternal and paternal)
4. Additional information sources:
 - a. Records of prenatal outpatient visits and laboratory studies
 - b. Records of the mother’s current and prior hospitalizations
 - c. Labor and delivery record
 - d. Newborn records created by nurses and other personnel
 - e. Direct communications from the obstetrician, midwife, and nurses
 - f. Interviews with the mother and other family members

In the era of transition from written to electronic health records, one must be cautious about “lost information” or misinformation inadvertently “carried over” between documents. Ideally, systems should be in place to ensure that the pediatrician responsible for the newborn is directly informed about high-risk conditions in a timely manner. However, the pediatrician has an independent responsibility to utilize information available in the maternal record to assess for potential high-risk issues. An outline of expected relevant prenatal and newborn history is presented in [Table 25.1](#).

It is essential to have a systematic approach to the collection and recording of the history so that important information is never presumed known when it is actually missing and/or when information becomes overlooked and thus neglected. This is particularly important when information gathering is interrupted and/or

TABLE 25.1 Components of an Emergency Prenatal and Newborn History

| Category | Components |
|--------------------------|--|
| Maternal identification | Age, gravida, parity, weeks in gestation |
| Maternal medical history | Significant illness, medications |
| Current pregnancy | Singleton or multiple fetuses |
| | Pertinent results of laboratory tests and studies |
| | Fetal growth (IUGR, LGA; hydrops) |
| Labor | Rupture of membrane (duration) |
| | Amniotic fluid (oligohydramnios/polyhydramnios; bloody; purulent; meconium; foul smelling) |
| | Signs of infection (maternal fever, elevated WBC count, tachycardia, uterine tenderness) |
| | Fetal tracing (tachycardia, decelerations, etc.) |
| Delivery | Indication for emergency (abruption; preeclampsia, fetal distress/intolerance to labor) |
| | Route of delivery |
| | Method of anesthesia (general vs. local) |
| | Medications administered |

IUGR, Intrauterine growth restriction; LGA, large for gestational age; WBC, white blood cell.

disjointed because of the need for immediate intervention to stabilize a newborn. For example, the pediatrician paged to attend the emergency delivery of a fetus in distress must focus information gathering, in just those few available minutes, on what is directly relevant to prepare for resuscitation.

For both the stabilized newborn sent to room with the mother and the critically ill newborn admitted to the NICU, one must quickly return to the systematic approach for collection and recording of the history. For example, if the mother does not have a documented negative test result for hepatitis B infection, the pediatrician may need to ascertain the hepatitis B status of the mother so that the hepatitis B vaccine can be administered within the recommended 12 hours after birth. Otherwise, for the healthy newborn, history gathering at the time of the initial encounter after birth will emphasize the prenatal history (including maternal and family history), the delivery and neonatal transition, the initiation of feeding, and any symptoms or parental concerns that have manifested themselves since birth.

During the initial evaluation, the pediatrician is expected to identify the following:

1. Risk factors for medical problems that may develop in the first few days of life (e.g., early-onset neonatal sepsis, severe hyperbilirubinemia)
2. Risk factors for psychosocial problems that may preclude safe discharge home

Although gathering the history and performing the physical examination are distinct activities and described in separate sections

of a pediatrician's documentation, they are not performed in isolation. Knowledge of specific concerns, events, and risk factors in the history should prompt a more focused or detailed examination of the relevant body region or organ system.

Clinical example: A newborn of a diabetic mother delivered with use of forceps and noted to have shoulder dystocia.

Pediatrician action: More detailed head, clavicular, and neurologic examinations.

Conversely, specific questioning prompted by physical examination findings will often elicit information that was not volunteered in the earlier routine history gathering, such as a family history of a specific anomaly.

Clinical example: An abnormal rhythm auscultated on examination with follow-up ECG findings suspicious of a prolonged corrected QT interval.

Pediatrician action: Query the parents regarding family history of sudden death, syncope, and/or early neonatal/infant death presumed to be due to sudden infant death syndrome.

Because of the potential of early-onset neonatal sepsis for morbidity and death, the presence or absence of risk factors for it should be assessed as part of the initial evaluation for every newborn.

The risk factors for early-onset sepsis include:

- Prematurity (<37 weeks' gestation) or low birthweight (<2500 g)
- Prolonged rupture of membranes (≥18 hours)
- Maternal body temperature of 38°C or higher, uterine tenderness, foul-smelling or purulent amniotic fluid, an elevated maternal white blood cell count or left shift, and fetal or maternal tachycardia
- Maternal vaginal colonization with group B streptococci unless adequate intrapartum prophylaxis was administered or the fetal membranes were intact until birth by cesarean delivery (CDC, 2010)
- Maternal urinary tract infection due to group B streptococci (*Escherichia coli* urinary tract infection is also a potential risk factor.)
- Poor fetal tolerance of labor
- Unexplained need for resuscitation at birth
- Delayed/"slow" extrauterine transition (noted by persistence of abnormal vital signs after birth)

After completion of the initial evaluation, it is important to document the history, physical examination findings, and laboratory study findings obtained. This information is the data used for crafting the newborn's assessment and plan of care. Once documented, the assessment and plan also become part of the ongoing newborn history. It is also important to know that the initial evaluation greatly informs the predischARGE evaluation, particularly if it is performed by two pediatricians. For the predischARGE evaluation, the prenatal and perinatal history will have already been documented and reviewed, so the pediatrician can direct his/her attention to the interval history (mostly collected from the nursing records and the parents). Knowledge of this information is critical in determining if the newborn can be discharged home safely.

Physical Examination Considerations

No matter how experienced the pediatrician is, every examination of a newborn adds to or refines one's appreciation of the wide ranges of variation in common and benign conditions observed. It also enhances the comfort level of the pediatrician for maintaining an appropriate level of vigilance to detect the abnormal newborn "hiding" amid the healthy ones. Repeated physical examinations

continually refine and merge the pediatrician's efficiency and thoroughness.

The examination of the healthy newborn entails a complete physical examination in the sense that all parts of the body are examined. However, it is impractical to exhaustively explore and explicitly document all possible findings. Fortunately, there are multiple opportunities to perform an examination and note pertinent findings, including:

1. Birth
2. Admission to the newborn nursery
3. Targeted/problem-directed evaluation
4. Daily follow-up encounter
5. Discharge from hospital or on follow-up home or office visits

Examination at Birth and Delivery Room Disposition

At the time of birth, attention focuses on the initiation of appropriate respiratory and cardiovascular stability. Ascertaining successful adaptation versus the need for ongoing resuscitation is described in more detail in Chapter 24. The newborn whose condition remains unstable or who has major anomalies that are apparent on initial inspection will usually be transferred to a NICU for further evaluation and management. However, it is reasonable for the pediatrician in attendance at the delivery to attempt the following brief assessment as feasible:

1. Presence of gross dysmorphic features
2. Auscultation for a potentially pathologic heart murmur
3. Patency of the anus

The newborn whose condition stabilizes after delivery, with or without intervention, is immediately evaluated to determine whether he/she can remain with the mother. This examination centers on determining adequacy of the cardiorespiratory transition and inspecting the newborn for congenital anomalies that may indicate a need for admission to a NICU or observation/stepdown unit. These latter inspections include the following:

1. Passage of a thin catheter through both nostrils to evaluate the newborn for potential choanal atresia
2. Passage of a thin catheter into the stomach to evaluate the newborn for potential esophageal atresia (with or without tracheoesophageal fistula)
3. Evaluation of the newborn for imperforate anus/anal patency

For routine deliveries of healthy newborns, this examination can also be performed by the obstetrician or nurse-midwife. If the pediatrician is present, an expanded examination can serve as the nursery admission examination. However, there is typically consideration for practices that encourage immediate bonding of the newborn and mother during the "golden hour" of transition after birth as well as initial breastfeeding attempts.

Nursery Admission Examination

For the healthy newborn this examination is done after the newborn completes transition and usually by 24 hours after birth. A complete physical examination at this time is designed to efficiently detect problems that were initially unapparent or are likely to soon develop. The pediatrician is again reminded that identification of historical risk factors or the detection of symptoms or abnormalities requires appropriate expansion of the basic examination (where indicated) to focus additional attention on the areas relevant to the developing differential diagnosis.

Targeted or Problem-Directed Evaluation

When the pediatrician is called to evaluate a newborn because of specific symptoms or concerns, the examination will naturally

focus on aspects relevant to those issues. Because of the notoriously nonspecific nature of many newborn symptoms, even the targeted examination will often need a wide focus to adequately inform the potentially wide differential diagnosis.

Daily Follow-Up Encounter

The daily follow-up examination for the newborn can be abbreviated but must always be guided by the newborn's overall condition. Areas of active attention should include the newborn's neurologic and cardiorespiratory status, hydration state, feeding and elimination patterns, and evaluation for jaundice.

Nursery Discharge Examination

Although similar in scope to the initial evaluations, the discharge examination has a slightly altered emphasis, based on the following:

1. Additional information provided during observation in the hospital
2. Determining whether the newborn is ready for routine care at home

The discharge examination is a complete physical examination. However, it is typically unnecessary to repeat a search for physical anomalies that do not change with time (e.g., examination of the oral cavity for cleft palate or the eyes for the red retinal reflexes) if they were not previously identified. If a different pediatrician performs the discharge examination, it is often more efficient to repeat the entire examination than to verify the completeness of previous examinations performed by different pediatricians. For hospital admissions of 24 hours or less, a combined admission–discharge examination is appropriate.

Performance of Examination

Approach to the Newborn Examination

An ongoing challenge of the newborn examination is the need to maintain efficiency, thoroughness, and a high level of vigilance while simultaneously projecting an attitude of calming reassurance. The air of appropriate reassurance reflects the reality that the overwhelming majority of newborns in the nursery are healthy. However, the repetition of evaluating normal newborns and practicing calming reassurance should never promote complacency.

Although an experienced examiner may detect many abnormalities by pattern recognition alone, even an expert can miss important findings by foregoing the disciplined and systematic approach advocated here. Still, the desire to ensure that no essential aspect of the examination is missed or slighted needs to be balanced with the newborn's tolerance for handling. It may seem easier to avoid omissions if the pediatrician always performs the examination in the same sequence. Unfortunately, a rigid approach that fails to adjust to the state and activity of the individual newborn may yield a suboptimal examination that is inefficient, inaccurate, and unnecessarily stressful for the newborn, parent, and examiner.

Environment

The environment in which the examination is performed can significantly affect the reliability of the results/findings via effects on the examiner and/or the baby. An optimal examination environment should be prioritized and maintained as much as possible. When this is not reasonably feasible, the examiner must be aware of the limitations produced by a suboptimal environment and adjust the approach to the examination to compensate, arrange

for the newborn to be moved, or defer selected parts of the examination when appropriate.

Important environmental considerations include:

1. Lighting
2. Temperature
3. Background noise
4. Other distractions (improper bed height/position, lack of appropriate equipment, parental and/or nursing queries, etc.)
5. Newborn's physiologic state (hungry, crying, etc.)

The healthy newborn is typically examined in a warmer bed in either the delivery room or the newborn nursery or in a bassinet in the mother's room. An open warmer bed provides the best access, allowing the newborn to be kept warm while completely undressed during the examination. However, the examination is often done with the newborn in a bassinet, starting with the newborn dressed in at least a shirt and hat, and wrapped in blankets.

An adequate well-baby examination can be performed under those basinet conditions, but the sequence of the examination should be modified to minimize the time the newborn is fully undressed. The examiner must take extra care to ensure that the examination is complete and the entire skin surface is visualized at some point during the examination.

Performing the examination in the presence of the parents allows the examiner to show how the newborn responds to handling and to demonstrate immediately any findings that require explanation or reassurance. Watching the examination may stimulate the parents to ask questions that might otherwise not occur to them until later, and it provides the physician with an immediate opportunity for further education. On the other hand, interruptions from parents and other family members can interfere with the examiner's train of thought, risking inadvertent distraction and omissions.

In large, busy nurseries, it may be more practical for the pediatrician to examine a series of newborns in the nursery and then report the results of the examination to each set of parents afterward. Specific findings are ideally demonstrated to the parents in real-time, if appropriate. Regardless of whether the parents are present for the examination, the results of the examination should be communicated promptly. Parents may be anxious about findings that the pediatrician believes are of little consequence and vice versa. Prompt and sensitive communication of the examination findings help to build parents' trust, whereas delayed or poor communication can undermine the parents' relationship with the physician and the hospital.

Evaluation of Gestational Age

If the obstetric estimate of the gestational age (GA) is uncertain or appears unreliable, the GA of the newborn can be estimated on the basis of physical examination criteria. This is important for determining highly relevant and pertinent information that will affect management and care. This includes an assessment of whether the patient is small for his/her GA or large for his/her GA. No individual feature is a reliable guide to the GA, but scoring systems that use multiple features of physical and neuromuscular maturity have been evaluated extensively (Amiel-Tison, 1968; Dubowitz et al., 1970). The Ballard score is probably the one most widely used in contemporary practice (Ballard et al., 1991). Detailed descriptions and a video demonstration of this examination are available at <http://www.ballardscore.com>. Pediatricians can also choose to use <http://www.medcalc.com/ballard.html> to assist them in calculating a Ballard score.

Determination of Key Metrics

The physical examination of the newborn includes measurements of the weight, length, and head circumference, which must be compared with standardized growth data (Fig. 25.1) to determine whether the newborn is small (<10th percentile), appropriately sized, or large (>90th percentile) for his/her GA (Battaglia and Lubchenco, 1967). For newborns born at less than 37 weeks' gestation, one should consider referencing the Fenton growth charts (Fig. 25.2).

The vital signs provided by nursing (body temperature, heart rate, and respiratory rate) may be reviewed, but the pediatrician should also note the heart rate and respiratory rate at the time of examination. The blood pressure is not routinely measured in healthy newborns, but the blood pressure should be checked in all four extremities if the history or examination suggests a circulation problem.

Of the standard physical newborn examination techniques, observation is often underappreciated and overlooked. Palpation and auscultation are also important, although percussion is of relatively limited use. The routine newborn examination does include specific physical maneuvers for examining the hips and for eliciting a variety of reflex responses.

A stethoscope, an ophthalmoscope, and a tape measure are the only pieces of equipment generally needed. A source of light for transillumination is helpful for specific purposes. Pulse oximetry can enhance early detection of critical congenital heart disease. In September 2011, US Secretary of Health and Human Services Kathleen Sebelius suggested that pulse oximetry screening for critical congenital heart defects be added to the Recommended Uniform Screening Panel for newborns before they are released from a hospital or birthing facility. (Martin et al., 2013). Several states have already passed laws to make this practice the standard of care in the initial newborn period. Screening is typically performed by appropriately trained staff 24–48 hours before discharge.

Initial Observation

Before approaching or touching the newborn, the pediatrician should stop and observe the newborn in an undisturbed state, making note of the following:

1. State of alertness or sleep
2. Color of visible portions of the skin and mucous membranes
3. Respiratory rate and any audible sounds or signs of increased work of breathing
4. Tone and posture
5. Spontaneous activity
6. Quality of cry and symmetry of facies when crying (if applicable)
7. General impression of whether the newborn is sick or healthy

These observations provide valuable information and should be repeated intermittently throughout the examination to compare and contrast them with the pediatrician's initial impressions. Attuning to the patient's state and responses can greatly facilitate the physical examination and make it less stressful for the newborn and less time-consuming for the examiner. The newborn generally responds more slowly to a stimulus than an older child or adult, and the response tends not to remain localized to the area of the stimulus.

Clinical example: Gentle touch of the face or extremity of a sleeping newborn, or merely loosening a blanket, typically results in some limited initial movement of the area touched,

www.ucalgary.ca/fenton

waking the newborn. With the newborn sleeping or in a quiet alert state, the examiner will usually begin by gently uncovering the chest. Depending on the type of clothing the newborn is wearing, it may be best at first to lift the shirt or gown just enough to slide the stethoscope underneath. Heart sounds and soft murmurs, if present, can easily be obscured by crying or the movement of fabric underneath the stethoscope. This may also be exacerbated by the relatively rapid respiratory rate for newborns as compared with adults and older children. Typically, the precordial area is auscultated first. If the newborn remains quiet, other locations on the chest can be auscultated for breath and heart sounds. The abdomen can also be assessed for the presence of bowel sounds. If the newborn is already crying or awakens and starts crying vigorously, auscultation can be deferred in favor of other parts of the examination. Once those have been completed, the newborn can be soothed and comforted back into a quiet resting state to complete auscultation.

In examining patients, one must remember that newborns are temperature sensitive. Ideally, the entire newborn should be exposed during an examination to inspect the newborn for skin abnormalities and dysmorphic features. However, there is a benefit from partially disrobing the newborn in sections as the examination progresses to facilitate maintenance of temperature and otherwise accomplish this goal.

Example Examination Sequence

1. Observation (is the baby sick or well?)
2. Auscultation of the anterior chest and abdomen (if the newborn is quiet and cooperative)
3. Inspect and palpate the head (the back of the head and neck will be inspected later).
4. Gently turn the head to each side (noting any restricted range of motion).
5. Inspect each ear when the head is turned.
6. Palpate the neck and clavicular areas (for masses and/or crepitus).
7. Determine overall features of facial shape and symmetry.
8. Confirm the presence or absence of abnormal findings involving skin, eyes, nose, mouth, and oral cavity.
9. Assess respiratory pattern.
10. Inspect and palpate the anterior chest and abdomen (including the umbilicus).
11. Open the diaper and palpate the femoral pulses.
12. Examine the genitalia and perineum.
13. Inspect the lower extremities for abnormal positioning to check alignment, plantar grasp, and the Babinski reflex (start by placing the thumbs on the soles of the feet with the fingers around the back of the ankles).
14. Perform the Barlow and Ortolani maneuvers.
15. Lift and abduct the legs into a frog-leg position to provide a full view of the perineum and anus. Evaluate the newborn for appropriate positioning of the anus and its patency.
16. Inspect the genitalia by gently retracting the labia majora in females or depressing the skin at the base of the penis in males. Inspect and palpate the scrotum and testes. Refasten the diaper.
17. Take an unobstructed observation of the overall shape, symmetry, and movements of the arms and hands (shirt/clothing removed).
18. Palpate each whole arm gently, starting with one of the examiner's hands on each of the baby's shoulders, and then slide down to the baby's hands, noting any swelling or discontinuities.

19. With the newborn supine, turn the head to elicit the asymmetric tonic neck reflex on each side.
20. Inspect the hands, fingers, nails, and palms. If the newborn's hand is tightly fistled, do not attempt to pry the fingers open. Instead, gently flex the wrist to 90 degrees, which will cause the fingers to relax naturally. Inspect the palms, and then elicit the palmar grasp reflex.
21. Without releasing the baby's hands, one can then perform the pull-to-sit maneuver. The pediatrician places his/her hand behind the newborn's head and neck to provide support as the newborn is gently lowered back toward the bed. When the newborn's head and shoulders are a few inches from the bed, the examiner drops his/her hand rapidly to elicit the Moro reflex. (Parents may be alerted to this portion of the examination to avoid unnecessary distress/anxiety.)
22. Next, place the hands on either side of the chest, under the arms at the shoulders, and raise the baby to an upright position. Note the strength and tone of the shoulder muscles.
23. Lower the newborn, still in an upright position, and try to elicit the supporting and stepping reflexes.
24. Turn the newborn to a prone position, suspended on the examiner's hand. Observe the newborn's posture and tone, and elicit the incurvation response. (Again, explanation in advance of these actions to parents who may be observing is helpful.)
25. Inspect the newborn's back, from the vertex of the head down to the sacrum (pulling the diaper down, if needed).
26. Gently place the newborn back in the crib, and fully redress the newborn. Attempt to successfully soothe newborn by swaddling if the newborn has cried during the more active portions of the examination.
27. Red reflex examination can be performed at this time or at any suitable time when the eyes are open spontaneously.

The previous sequence presumes a healthy newborn with findings within the range of normally accepted limits. With any abnormal and/or questionable findings, additional investigations are warranted, and the results should be documented. Occasionally, it may be preferable to defer portions of the examination. Any such decisions and/or limitations of the examination should be clearly documented, with the need for reexamination listed explicitly in the plan of care.

Detailed Physical Examination

Skin

To examine the skin of a newborn, the lighting must be adequate and consistent. Ambient natural light is best. Phototherapy lights must be turned off during the examination. Even if the skin examination is performed simultaneously with regional evaluations of the body, it is important to make a specific note of the skin findings as a separate documentation, particularly if abnormalities are seen. The size, shape, location, distribution, and time course of lesions are all important for differential diagnosis. Documentation should clearly state how measurements of skin findings/lesions were obtained to facilitate reproducibility by other examiners.

The entire skin surface should be inspected during the course of the examination, with attention to the following:

1. Color
2. Moisture
3. Temperature
4. Texture
5. Elasticity properties
6. Pattern and depth of skin creases
7. Presence and character of any lesion

Nails and hair (considered a skin appendage) are inspected along with the skin, with attention to similar findings:

For nails:

1. Color
2. Size
3. Shape
4. Presence of lesions

For hair:

1. Growth pattern
2. Color/discoloration
3. Texture/changes in texture
4. Distribution of scalp and body hair

What affects the color of newborn skin?

1. Newborn's basic skin pigmentation
2. Adequacy of tissue perfusion
3. Amounts of oxygenated and deoxygenated hemoglobin in the local circulation
4. (Optional): internal staining of skin by extravasated blood or pigmented molecules such as bilirubin; external staining by in utero exposure to meconium or postnatally by foreign substances applied to the skin

With polycythemia (excessive hemoglobin levels) a deep red or purple-red color (plethora) of the skin is seen. Paleness/pallor may be caused by anemia or poor perfusion. Central oxygenation is usually best evaluated by observing the color of the tongue and oral mucous membranes because lip color can be misleading. Visual detection of central cyanosis requires approximately 5 g of desaturated hemoglobin per 100 mL of blood and may not be apparent in the presence of significant anemia.

Acrocyanosis (cyanosis of the perioral area, hands, and feet) is common in the first 24 hours after birth or if the newborn is cold. It is due to relatively poor perfusion of those areas, resulting in increased O₂ extraction by the tissues and an increase in the concentration of deoxyhemoglobin. Because skin color is dependent on perfusion, it can be a sensitive indicator of systemic perfusion. However, the newborn's peripheral color can vary markedly and rapidly with activity and the local environmental temperature.

Cutis marmorata (transient mottling of skin of the extremities and trunk) is also a common skin finding in newborns in response to cold. However, if mottling does not resolve with warming, other conditions should be considered, such as hypothyroidism.

Harlequin color change is a striking but infrequently observed transient asymmetry of color and perfusion, in which one side of the body is vasodilated, with a clear line of demarcation at the midline.

Jaundice in newborns is characterized by a yellow-orange skin color caused by elevated unconjugated bilirubin concentrations. When present, jaundice typically becomes apparent in the face first and then progresses distally with rising bilirubin concentrations. However, visual inspection is not a reliable means to determine the severity of unconjugated hyperbilirubinemia nor can it be distinguished from pathologic conjugated hyperbilirubinemia. Furthermore, even expert examiners have difficulty visually assessing newborns for jaundice across ethnically diverse populations. For example, jaundice may be underestimated in African-American and Latino newborns and overestimated in Asian newborns because of variations in skin pigmentation.

Erythema neonatorum is typically viewed as a transient period of generalized erythema noted a few hours after birth. It is usually observed by the parents, often during a bath or with vigorous crying. It tends to resolve within minutes to an hour and appears to be associated with successful completion of neonatal transition

of the circulation. It rarely recurs with the same intensity after the first episode (Fletcher, 1998).

Skin creasing is affected by both development and movement:

1. Increased creasing: constriction of fetal movement (e.g., fetus near term)
2. Absent creasing on the palms or soles of a term or near-term newborn: consider prolonged lack of movement secondary to a neuromuscular disorder.
3. Effect of edema: stretches the skin and obscures normal skin folds and creases; skin pits with gentle pressure; distribution of edema is affected by gravity and changes with patient positioning. Lymphedema (as in Turner syndrome) tends to *accentuate* skin creasing and is less affected by gravity (Fletcher, 1998).

Iatrogenic trauma and injuries (in utero or at delivery) are common. Cutaneous findings include scars from injury by an amniocentesis needle; minor lacerations and abscesses from fetal scalp electrodes or fetal blood gas sampling; scalpel lacerations during cesarean section; and ecchymoses and abrasions from application of forceps or vacuum.

Trauma can also occur from external pressure on the fetus during labor, particularly over bony prominences. This may lead to the development of subcutaneous fat necrosis, an uncommon condition hypothesized to be caused by hypoxic injury to fat and manifested by firm, subcutaneous nodules and plaques (Cohen, 2008). The lesions usually resolve spontaneously after several months but can become inflamed and fluctuant. On occasion, they are associated with later development of significant hypercalcemia.

Aplasia cutis congenita is a focal lesion characterized by congenital absence of some or all layers of skin (Fig. 25.3). It may occur sporadically, but it can be associated with chromosomal defects or other malformations (Kos and Drolet, 2008). It occurs most often on the scalp near the vertex and can be mistakenly presumed to be the result of a traumatic injury.

Some common and uncommon skin conditions observed in the newborn are outlined in Box 25.1. Fortunately, most of the skin findings encountered during a healthy newborn's examination are typically benign.

• **Fig. 25.3** Aplasia Cutis Congenita. Lesions are usually single. Two adjacent lesions near the vertex—one bullous and one membranous—can be appreciated. (From Rudolph AJ. *Atlas of the Newborn*. Vol 4. Hamilton, Ontario, Canada: BC Decker; 1997:30.)

• BOX 25.1 Common and Uncommon Causes of Skin Lesions in Neonates

Pustular, Vesiculopustular, and Vesiculobullous Lesions

- Common or benign: erythema toxicum neonatorum, transient neonatal pustular melanosis, miliaria crystallina, miliaria rubra, sucking blisters, neonatal acne (benign cephalic pustulosis)
- Infectious: herpes simplex, varicella, staphylococcal pustulosis, bullous impetigo, congenital candidiasis, syphilis, scabies
- Chronic or recurrent: epidermolysis bullosa, mastocytosis, epidermolytic hyperkeratosis, acropustulosis of infancy
- Positive Nikolsky sign: epidermolysis bullosa, staphylococcal scalded skin syndrome
- Other: incontinentia pigmenti

Nodules and Plaques

- Common or benign: milia, Epstein pearls, Bohn nodules, sebaceous hyperplasia
- Yellow: sebaceous nevus, juvenile xanthogranuloma
- Brown or black: congenital pigmented nevus, epidermal nevus
- Other: subcutaneous fat necrosis, dermoid cyst, fibroma, infantile myofibromatosis, hamartomas, malignant tumors, leukemia

Papulosquamous and Scaling Lesions

- Common or benign: physiologic desquamation
- Healthy newborn: atopic dermatitis, contact dermatitis, seborrheic dermatitis, local candida dermatitis, psoriasis
- Ill newborn: acrodermatitis enteropathica, Langerhans cell histiocytosis, syphilis
- Other: ichthyosis syndromes, collodion baby, harlequin baby

Erosions and Ulcerations

- Common or benign: sucking blisters, traumatic injury (e.g., scalp electrode, diaper erosions, reaction to adhesives)
- Other: aplasia cutis congenita, herpes simplex, epidermolysis bullosa, toxic epidermal necrolysis

Altered Pigmentation

- Common or benign: Mongolian spots, transient neonatal pustular melanosis, isolated café au lait macules
- Increased pigmentation: Mongolian spots, transient neonatal pustular melanosis, café au lait macules, lentigines, incontinentia pigmenti
- Decreased pigmentation: ash leaf macule, nevus depigmentosus, piebaldism, albinism
- Purpuric or erythematous: petechiae, dermal hematopoiesis (“blueberry muffin” lesions), neonatal lupus erythematosus

Vascular and Lymphatic Lesions

- Common or benign: nevus simplex or salmon patch, petechiae on the presenting part, small hemangioma
- Other vascular: complicated hemangioma, vascular malformation, port-wine stain
- Lymphatic: cystic hygroma, lymphangioma, lymphedema

Tutorial videos and demonstrations from the University of Utah (Paul Larsen, University of Nebraska, College of Medicine, and Susanne Stensaas, University of Utah School of Medicine).

If unusual or unfamiliar lesions are seen on the examination that fall outside the pediatrician's experience, consultation with an appropriate subspecialist should be arranged, and any appropriate additional studies should be initiated.

Erythema toxicum neonatorum (also known as erythema toxicum and “e. tox.”) is the most common rash in the newborn—observed in up to 70% of term newborns (Howard and Frieden, 2008; Lucky, 2008). The characteristic lesion is an isolated elevated

• **Fig. 25.4** Erythema toxicum neonatorum with erythematous macules, wheals, and pustules. Pustules predominate in this example. At times, patchy or confluent areas of erythema occur without pustules. (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:88.)

erythematous papule or pustule that is 1–2 mm in diameter and surrounded by an irregular area of erythema that is slightly larger at 1–3 cm in diameter (Fig. 25.4). They are occasionally present at birth but typically are first noted at 1–2 days of life. Although predominantly noted on the face and trunk, they can appear anywhere on the body *except* the palms and soles. New lesions may continue to appear for approximately 1 week while older lesions are simultaneously resolving. When extensive, the lesions can occur in clusters or become nearly confluent. Diagnosis can usually be made by appearance alone, but a scraping of the pustule will reveal an almost pure infiltrate of eosinophils if confirmation is needed for atypical cases.

Transient neonatal pustular melanosis is a benign and self-limited skin manifestation defined by the appearance and evolution of three distinct phases of skin lesions (Howard and Frieden, 2008; Lucky, 2008; Fig. 25.5). Initially, a superficial vesicopustule appears. It will then rupture and leave a fine rim of scale around the unroofed pustule. There is no associated erythema (unlike the erythema seen with erythema toxicum). The final stage is a hyperpigmented macule that gradually disappears and may be described as *freckles*. Different stages may be simultaneously seen on examination of the skin. The condition is most commonly seen in African-American newborns but is also recognized in other ethnically diverse newborns of color. In some cases, only the second or third stage is seen at birth, the initial stage presumably having occurred in utero.

Miliaria crystallina happens after superficial obstruction of the sweat ducts and produces small, crystal-clear vesicles that resemble water droplets (Fig. 25.6). It is classically seen where newborns live in warm climates or are febrile. The vesicles are fragile and can be easily removed by wiping of the skin with a soft damp cloth (Howard and Frieden, 2008; Lucky, 2008).

Miliaria rubra, also called *heat rash* or *prickly heat*, results from sweat duct obstruction deeper in the epidermal layer. This type of “rash” typically presents after the first week of life. It is mentioned in this context because it can occasionally appear as a pustular rash that mimics skin findings caused by cutaneous staphylococcal, candidal, or herpes simplex infection.

Sucking blisters and calluses result from vigorous sucking on a hand or forearm in utero. They can be visually quite impressive

• **Fig. 25.5** Transient Neonatal Pustular Melanosis. The first stage consists of small superficial pustules, without inflammation (A). Scales that rim the location of a pustule (comprising the second stage) may be seen at birth without evident pustules (B) or may develop postnatally after pustules have ruptured (C). Small hyperpigmented macules remain in the final stage (D), gradually fading over weeks or months. (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed, Philadelphia: Saunders; 2008:89.)

• **Fig. 25.6** Miliaria Crystallina. The tiny, clear vesicles resemble water droplets, with no signs of inflammation. (From Rudolph AJ. *Atlas of the Newborn*. Vol 4. Hamilton, Ontario, Canada: BC Decker; 1997:13.)

• **Fig. 25.7** Neonatal Cephalic Pustulosis (Neonatal Acne). Small, red papules and pustules are seen on the cheeks and forehead, with some extension into the scalp. Comedones are absent. (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:90.)

and cause a tense, fluid-filled blister. Once the blister ruptures, it forms an erosion or a callus. The lesion is most often solitary (occasionally bilateral) and is without inflammation. This is similar to the sucking pad or callus that can develop on the newborn's lips as a result of vigorous and frequent nursing.

Neonatal cephalic pustulosis ("neonatal acne") may occasionally be seen at birth. However, it has a mean onset of appearance at 2–3 weeks of life (Howard and Frieden, 2008; Lucky, 2008). It is characterized by inflammatory, erythematous papules and pustules located primarily on the cheeks with extension over the face and into the scalp (Fig. 25.7). Sometimes it is difficult to confidently

distinguish it from miliaria rubra. Fortunately, both are benign conditions. Therefore neither definitive diagnosis nor biopsies are warranted.

Infections presenting with skin lesions are relatively uncommon in the immediate newborn period but should be considered in the differential diagnosis, particularly for newborns who may be slightly premature:

1. Congenital candidiasis typically occurs immediately after birth (appearing on the first day). It is a papulovesicular eruption

• **Fig. 25.8** Congenital Candidiasis. The rash may be a diffuse, erythematous pustular eruption (A) or may have diffusely distributed but distinct pustules (B). In premature newborns, a diffuse scald-like erythematous dermatitis may be seen (not shown). (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:214.)

that progresses to pustules, followed by crusting and desquamation (Fig. 25.8). Lesions can be widespread and may appear on any part of the body, including the palms and soles (Darmstadt et al., 2000; Carder, 2008).

2. Thrush and candidal diaper dermatitis are distinct from congenital candidiasis. These infections are not seen immediately after birth but may present in the first week of life. Superficial skin infections of *Staphylococcus aureus* may also present during this time frame.
3. Neonatal herpes simplex is unlikely in the first few days after birth unless there is a history of severely prolonged rupture of membranes. However, it must be considered whenever vesicles are seen in the newborn. The skin lesions of herpes simplex start as small, 2–4-mm vesicles on an erythematous base. After 1–3 days the lesions become pustular and develop an eschar (Friedlander and Bradley, 2008; Fig. 25.9). The mucosal lesions are usually shallow ulcerations.
4. “Blueberry muffin” skin lesions of congenital rubella and cytomegalovirus (CMV) infection are caused by dermal hematopoiesis. When caused by infection, these lesions are unlikely found in isolation. Affected newborns typically have multiple stigmata of congenital infection, including growth retardation, microcephaly, and hepatosplenomegaly. However, one might separately include congenital histiocytosis in the differential diagnosis for this skin lesion.
5. Congenital syphilis skin findings are rarely seen, but they classically involve the palms, soles, perioral and anogenital areas (Dinulos and Pace, 2008; Howard and Frieden, 2008).

An additional difficulty is the *variable* presentation of the syphilitic rash. It may appear in papulosquamous, vesiculobullous, macular erythematous, annular, or polymorphous forms. However, desquamation limited to the palms and soles, with no rash or peeling elsewhere, is highly suggestive of congenital syphilis (Fig. 25.10). Given the resurgence of syphilis in some urban areas, the astute examiner should still maintain a watchful eye for this uncommon presentation of congenital syphilis.

Milia, Epstein pearls, and Bohn nodules are all forms of epidermal inclusion cysts (Lucky, 2008; Fig. 25.11):

1. Milia occur on the face and scalp in small numbers. They are smooth, firm, white papules with no associated erythema. They may be present at birth or appear somewhat later. They usually resolve within a few months.
2. Epstein pearls are larger inclusion cysts, which usually occur as distinct single lesions. Common locations include the central

• **Fig. 25.9** Herpes Simplex. (A) The first signs of herpes infection in this newborn were eroded vesicles at the corner of the mouth. (B) Herpetic vesicles on the face, scalp, and ear of a newborn with respiratory distress and hepatitis. (From Cohen B. *Pediatric Dermatology*. 3rd ed. Philadelphia: Mosby; 2005:36.)

hard palate, the foreskin, and the ventral surface of the penis and scrotum.

3. Bohn nodules are also larger inclusion cysts found on the alveolar ridge of the oral cavity.

Sebaceous hyperplasia occurs mostly on the face, especially the nose and upper lip. It is characterized by sheets of smooth, yellow-white papules with the regular spacing of involved follicles and no surrounding erythema (Fig. 25.12). Androgenic hormonal stimulation in utero causes this hypertrophy of the sebaceous glands. After birth it gradually resolves over several weeks.

• **Fig. 25.10** Desquamation on the palms (A) and soles (B) of a newborn with congenital syphilis. (From Rudolph AJ. *Atlas of the Newborn*. Vol 4. Hamilton, Ontario, Canada: BC Decker; 1997:108.)

Physiologic desquamation is frequently seen in term newborns at 1–2 days of age, particularly on the hands and feet. This is more pronounced in some postmature newborns (born later than 41 $\frac{1}{2}$ weeks). The dry, thickened skin cracks and peels extensively and then normalizes spontaneously without intervention in approximately 1 week. It is not typically confused with ichthyoses (rare inherited disorders of cornification) that manifest themselves in the neonatal period (Irvine and Paller, 2008).

Ichthyosis disorders include Harlequin ichthyosis (caused by mutations in the *ABCA12* gene) and “collodion babies” who appear encased in a thickened, shiny skin that resembles collodion, a phenotype associated with a number of different ichthyotic conditions.

Congenital dermal melanocytosis (“Mongolian spots”) are macular areas of a slate gray, blue-gray, blue-black, or deep brown color. The distinctive appearance is due to the presence of melanocytes located in the dermis, instead of their typical site at the dermal–epidermal junction. They most commonly occur on the lower back and buttocks but can occur on other extensor surfaces. The pigmentation tends to fade over several years but can persist without resolution (Gibbs and Makkar, 2008; Lucky, 2008). They are common in East Asian, East African, Native American, African-American, and Polynesian newborns and should not be confused with ecchymoses from nonaccidental trauma.

Dermal melanocytosis in the area of the first and second divisions of the trigeminal nerve is called the *nevus of Ota*. The *nevus of Ito* is a similar lesion occurring on the neck, upper back, and shoulders in the area of the posterior supraclavicular and lateral brachial cutaneous nerves. Unlike congenital dermal melanocytosis, these nevi do not become less pigmented with time. Rarely, malignant melanoma or malignant nevi can develop within them.

Café au lait macules are tan-brown macules that occur anywhere on the body. They are common as an isolated finding and generally benign. However, they can be markers of other conditions (Gibbs and Makkar, 2008). The presence of six or more café au lait macules

greater than 5 mm in diameter is considered presumptive evidence of neurofibromatosis type 1. Multiple large café au lait macules with irregular borders may be a manifestation of McCune–Albright syndrome.

Nevus simplex (“salmon patch”) is a benign vascular lesion consisting of erythematous macules or patches frequently seen at the nape of the neck (“stork bite”) or on the eyelids and glabella (“angel’s kisses”). Somewhat less frequently, it appears on the nose and upper lip (Lucky, 2008; Fig. 25.13). The lesions are caused by dilated capillaries in the upper dermis, with normal overlying skin. Facial lesions usually fade or resolve completely within 1–2 years, but 25%–50% of those on the neck persist throughout life (Lucky, 2008).

Petechiae after vaginal delivery of a healthy newborn on the presenting part (i.e., the part of the fetus closest to the pelvic inlet of the birth canal at the onset of labor) or on other areas of the body subjected to localized pressure during delivery are not unusual or concerning. A tight nuchal cord can cause extensive ecchymoses and petechiae on the entire head. Diffuse petechiae, however, are abnormal and suggest thrombocytopenia or platelet dysfunction.

Hemangiomas are soft, pink-red, compressible vascular tumors composed of proliferating endothelial cells. Small hemangiomas are recognized at or shortly after birth in 1%–3% of healthy term newborns and become apparent in 10% of all newborns by 1 month of age (Cohen, 2005). Hemangiomas are more common in female newborns (2:1) than in male newborns (9:1). The incidence is much higher (22%–30%) in preterm newborns weighing less than 1000 g but is only slightly higher (15%) in those weighing 1000–1500 g (Amir et al., 1986; Enjolras and Garzon, 2008). Infantile hemangiomas typically undergo a period of growth for 6–12 months, which is followed by spontaneous involution. Approximately 25% regress by 2 years of age, 40%–50% regress by 4 years of age, 60%–75% regress by 6 years of age, and 95% regress by adolescence (Cohen, 2005). Before the hemangioma

• **Fig. 25.11** Epidermal Inclusion Cysts. Milia are most commonly seen on the face (A) but can occur anywhere on the body. Epstein pearls occur on the midline of the hard palate, most commonly near the junction with the soft palate (B). Bohn nodules are found along the gum margins and on the lateral palate (C). Dental lamina cysts (not shown) are similar inclusions located on the crest of the alveolar ridge. (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:124 [A]; and Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:503–504 [B, C].)

• **Fig. 25.12** Sebaceous Hyperplasia. Sheets of tiny, white-yellow follicular papules, without inflammation, are seen on the nose. (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:87.)

• **Fig. 25.13** Salmon patches are commonly seen on the glabella, eyelids, nose, or upper lip, either singly or in all these locations (A) and on the nape of the neck (B). (From Eichenfield LF, Frieden IJ, Esterly NB, eds. *Neonatal Dermatology*. 2nd ed. Philadelphia: Saunders; 2008:95.)

becomes obvious, careful examination may reveal a precursor lesion manifesting itself as telangiectasias surrounded by an area of pallor, or it may be pale, erythematous, or ecchymotic-like macules and patches. In contrast, vascular malformations are nonproliferative lesions, usually present at birth.

Kasabach–Merritt phenomenon occurs in association with specific types of large vascular tumors that cause platelet trapping and severe thrombocytopenia. It is not associated with true hemangioma of infancy (Enjolras and Garzon, 2008).

Port-wine stains are capillary malformations evident at birth as pink or red patches that grow proportionately with the child and persist throughout life (Enjolras and Garzon, 2008). The initial pink-red color typically changes to a deeper red or purple hue with age. Approximately 10% of port-wine stains that involve the area supplied by the ophthalmic (V1) branch of the trigeminal nerve (Fig. 25.14) are associated with seizures, arterial brain malformations, and ocular abnormalities that are commonly referred to as Sturge–Weber syndrome (Enjolras et al., 1985).

Head

Scalp hair quantity in the newborn is highly variable, but abnormalities in the distribution, texture, and patterning of the hair are

potentially informative and should be documented. Hair usually forms a single whorl near the vertex, but double whorls occur in approximately 5% of newborns. Abnormal placement or the presence of more than two whorls may be a marker of abnormal brain development (Smith and Gong, 1974).

Caput succedaneum is a diffuse edematous swelling of the scalp caused by pressure during delivery that results in fluid accumulation external to the periosteum. The caput is boggy, has diffuse edges, is not limited by suture lines, and is most commonly located over the vertex. It is usually present at birth and resolves over several days.

Cephalohematoma is caused by hemorrhage *beneath* the periosteum. It forms a distinct, firm lateral mass that does not cross suture lines (Fig. 25.15). It may not be apparent until several hours after birth, and it often increases in size in the first 12–24 hours. It typically remains palpable for 2–3 weeks and may also develop a calcified rim.

• **Fig. 25.14** This newborn with Sturge–Weber syndrome has a port-wine stain in the distribution of the ophthalmic division of the facial nerve. (From Cohen B. *Pediatric Dermatology*. 3rd ed. Philadelphia: Mosby; 2005:49.)

Subgaleal hematoma is not confined by the periosteum and can involve massive loss of circulating blood volume due to the large potential space for hemorrhage to collect. Depending on the volume of blood that has accumulated, the hematoma can be palpated as a firm or fluctuant mass with poorly defined edges that may extend onto the neck or forehead. Large subgaleal hematomas are uncommon but are associated with high morbidity and mortality. Reasonable consideration for admission to the NICU for observation and evaluation should be considered.

Skull inspection and palpation for overall size, shape, and features of the skull should be done. Head circumference (maximal occipital–frontal circumference) should always be measured and plotted on an appropriate growth chart (see Fig. 25.2). Head circumference measurement is subject to error and often significantly affected by molding of the skull during labor. The head circumference measurement should be repeated if the result appears discordant with the visual examination or the newborn's weight and length—after molding has resolved. The soft tissue of the scalp should be examined for swelling, ecchymoses, and other evidence of birth-related injury and for iatrogenic injuries (application of a vacuum device, placement of scalp electrodes, fetal blood sampling, and lacerations with a scalpel during cesarean section).

The newborn's skull is composed of several bony plates, separated by sutures and fontanels so that the skull appropriately deforms during labor (Fig. 25.16). The entire surface of the skull should be palpated to identify the location and size of the major fontanels and assess it for discontinuities. The soft tissue over a fontanel should normally be flat; a raised or bulging fontanel suggests that intracranial pressure is increased. It is common to find palpable discontinuity at a suture because of vertical displacement of a skull bone relative to the neighboring one (molding). In some cases, one bone can truly override the other, but this must still be distinguished from the step-off of a displaced skull fracture.

Craniosynostosis is premature fusion of one or more of the cranial sutures and causes a variety of abnormal skull shapes, depending on which sutures are involved (Fletcher, 1998; Volpe, 2008). Fusion of the sagittal suture produces a narrow skull elongated in the anterior–posterior dimension (scaphocephaly or dolichocephaly). Fusion of the coronal sutures causes a widened skull that is shortened in the anterior–posterior dimension (brachycephaly). Unilateral closure of either a coronal or a lambdoid suture causes an oblique deformity (frontal or occipital plagiocephaly respectively). Closure of a metopic suture produces a triangular skull with a prominent, narrow forehead (trigonocephaly). Depending on the timing of the fusion, the skull

• **Fig. 25.15** Anterior (A) and posterior (B) views of a large cephalohematoma under the periosteum of the right parietal bone. (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:185.)

• **Fig. 25.16** The Major Sutures and Fontanels of the Newborn Skull. (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:175.)

shape may be abnormal at birth or become visibly deformed later. The fused suture typically has a palpable elevation or ridge, which must be distinguished from displacement of a normal suture caused by molding. In the absence of craniosynostosis or overriding sutures, normal mobility at a suture can be verified by gentle application of alternating pressure on the bones on either side of the suture line.

Craniotabes (or craniomalacia) is a softening of the skull, most commonly involving the parietal bones near the vertex. Gentle pressure on the involved bone produces a sudden collapse, with recoil when the pressure is released, similar to the way a ping-pong ball collapses when squeezed. It has usually been attributed to localized bone resorption or interference with ossification caused by prolonged pressure on the fetal skull from the maternal pelvis, but it may be associated with maternal vitamin D deficiency in some populations (Yorifuji et al., 2008).

Encephaloceles may be small soft-tissue masses or bulges of brain and/or the membranes surrounding it at the occiput or in the midline of the forehead near the bridge of the nose. Large encephaloceles and major neural tube defects should otherwise be obvious if present.

Face

The face and facial expressions should be observed throughout the examination. It is helpful to view the face from the front, in

• **Fig. 25.17** Anatomy of the External Ear. (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:285.)

profile, and looking down from the top of the head. Important characteristics to note include the symmetry and relative sizes, spacing, and orientation of the features. Expressiveness of the face, both at rest and during crying, should be noted. Specific attention should be paid to the ears, eyes, eyebrows, eyelids, nose and nasal passages, lips, palate, and mouth. Suggested abnormalities should be described as precisely as possible. Measurements of the facial features are not part of the routine newborn examination, and comparison with reference nomograms for suspected dysmorphisms should ideally be done in consultation with a geneticist.

Ears

The external ear is a relatively common site of minor anomalies. The external ear develops from the first and second branchial arches. Most of the pinna derives from the second branchial arch. The third arch contributes the tragus, antitragus, and anterior wall of the canal (Fig. 25.17). The position and orientation of each ear should be noted, as should the size, shape, and structure of the helix, and any signs of trauma. The ear is palpated to assess the firmness and recoil of the cartilage and to detect any masses or abnormalities of texture. The skin near the pinna is examined for skin tags, pits, and sinus tracts. Minor variations in the shape of the ear and earlobe are common, and they usually have only cosmetic significance. A lop ear is characterized by downward folding of the superior helix caused by underdevelopment of the upper third of the pinna. However, this needs to be distinguished from folding caused by positioning in utero. A cup ear is a protruding ear with an excessively concave concha. Microtia implies a severely dysplastic and malformed ear, and it is often associated with abnormalities of the middle ear and other malformations.

More than 95% of all newborns born in the United States are screened for hearing loss shortly after birth by automated testing of hearing before hospital discharge (American Academy of Pediatrics, 2007; US Preventive Services Task Force, 2008). The screening test is effective and allows early identification of hearing loss. However, there is concern for ways to address the

newborns who are lost to follow-up. Additionally, ongoing studies are evaluating the role of CMV testing with universal hearing screening given that CMV infection (even in asymptomatic newborns) may account for 20%–30% of newborns in whom hearing loss is diagnosed.

Eyes

As part of the inspection of the face, the size, spacing, and orientation of the eyes, eyelids, and eyebrows should be assessed:

1. Microphthalmos: entire eye is small
2. Microcornea: possible isolated finding in otherwise normal eye
3. Hypertelorism: spacing between the bony orbits is excessively wide
4. Telecanthus: inner canthi are displaced laterally, giving a false impression of hypertelorism
5. Hypotelorism: often associated with holoprosencephaly, trisomy 13, and other genetic abnormalities
6. Downslanting palpebral fissures: medial canthi are higher than lateral canthi.
7. Upslanting palpebral fissures: lateral canthi are higher than medial canthi.
8. Ptosis: difficult to reliably detect in the newborn (unless severe or unilateral); may be congenital or it can be caused by trauma or inflammation
9. Transient episodes of gaze disjugation are common in otherwise healthy newborns, but persistent eye deviation requires follow-up.
10. Obstruction at both ends of the lacrimal sac produces a mucocoele (or dacryocoele) that appears as a bluish subcutaneous mass that can be mistaken for a hemangioma or an encephalocele. Mucocoeles can sometimes extend into the nasal passages and cause respiratory distress.

Routine examination of the sclera, cornea, and internal portions of the newborn eye is often limited by the significant eyelid edema present in the first few days after birth. If corneas and conjunctivae cannot be adequately visualized during spontaneous eye opening or with gentle lid retraction, it is normally preferable to defer further examination until the swelling recedes.

11. Coloboma: congenital defect in eye formation; can affect any or all of the external or internal structures of the eye. Colobomas of the iris (frequently located inferomedially and producing a keyhole-shaped pupil) are the most common type visible on external examination. With examination, the lower lid of each eye should be retracted so that the entire pupil is visible, if not the entire cornea. Ophthalmologic evaluation of internal structures of the eye is advisable when colobomas are seen.
12. Glaucoma: cloudy corneas represent glaucoma until proven otherwise and require prompt ophthalmologic evaluation even if obvious enlargement of the cornea and globe (buphthalmos) is not present.
13. Subconjunctival hemorrhages are common in newborns, particularly after vaginal delivery. They do not indicate trauma unless other findings are present, so it is helpful to document their presence.

A red reflex examination of the eyes should be performed in all newborns before discharge from the nursery. It is normal when the reflections of the two eyes viewed both individually and simultaneously are equivalent in color, intensity, and clarity, and there are no opacities or white spots within the area of either red

reflex or both red reflexes ([American Academy of Pediatrics, 2008](#)). Problems potentially detected by the red reflex examination include cataracts, aqueous and vitreous opacities, and retinal abnormalities, including tumors and chorioretinal colobomas. Dark spots in the red reflex, a markedly diminished reflex, the presence of a white reflex, or asymmetry of the reflexes is an indication for immediate referral to an ophthalmologist with pediatric expertise ([American Academy of Pediatrics, 2008](#)). The red reflex examination is vital for early detection of vision-threatening and potentially life-threatening abnormalities, including retinoblastoma. Unfortunately, the sensitivity of the routine red reflex examination for retinoblastoma detection is low, and most retinoblastomas are first detected by family members, despite routine screening ([Abramson et al., 2003](#)).

Nose

The nose should be evaluated for the size, shape, and symmetry of the nostrils, columella, alae nasi, and bridge, root, and tip and inspected for deformations. Asymmetries of the nose caused by in utero compression are common and need to be distinguished from more serious conditions such as septal deviation (prenatal or birth trauma), nasal fracture, or other deformations.

Passage of a catheter beyond the nasopharynx via each nare usually rules out choanal atresia but does not ensure that the nasal passages are adequately sized for normal breathing. One can evaluate the quality and volume of airflow through each nostril by listening with the bell of a stethoscope (or by observing the deflection of a wisp of cotton placed under the nostril). As obligate nose breathers, newborns should breathe comfortably via each nostril separately with the mouth closed. This can be assessed by the examiner briefly occluding each nostril with his/her fingertip. If unilateral atresia or stenosis is present, the newborn will exhibit signs of distress when the patent nostril is occluded. Persistent flaring of the alae nasi may occur as the sole or initial symptom of mild respiratory distress, or it may accompany grunting and retractions. Appropriate intervention is indicated.

Mouth and Oral Cavity

The lips, perioral area, and oral cavity should be inspected both at rest and during crying. The shape of the philtrum should be evaluated when the mouth is relaxed, because stretching of the upper lip during crying can give a false impression of the flat philtrum suggestive of fetal alcohol syndrome. Perioral cyanosis is common and benign in normal newborns in the immediate newborn period. However, cyanosis of the tongue and mucous membranes is always abnormal and requires immediate investigation. A well-hydrated newborn will have mucous membranes that are moist and shiny with saliva. Excessive oral secretions can be caused by esophageal atresia or impaired swallowing. An anteriorly displaced and/or excessively short frenulum that restricts protrusion and/or elevation of the tongue can be a cause of maternal pain with breastfeeding and subsequent breastfeeding difficulties.

No instruments are typically needed for the oral cavity examination. Epstein pearls, Bohn nodules, and dental lamina cysts (see [Fig. 25.11](#)) are common and benign findings. Tonsils are normally inconspicuous in newborns. With some adjustment of head position, the entire palate and much of the pharynx is seen, especially if the newborn cries. The soft palate elevates symmetrically during crying if cranial nerves (CNs) IX and X are intact. The uvula is short but highly mobile. A bifid uvula may be an isolated finding, but a submucosal cleft palate must be excluded.

After inspection the oral cavity should be palpated with a gloved finger to assess the shape and integrity of the palate and to feel for natal teeth and masses. Although clefting of the lip and anterior palate are easily seen, palpation decreases the chance that a pediatrician misses an isolated cleft of the posterior palate. Palpation may elicit the sucking reflex, and this can be used to gauge the strength and coordination of sucking. Elicitation of a gag reflex is not usually done in healthy newborns but should be done if the newborn is neurologically depressed or has difficulty swallowing.

Neck

It is usually convenient to combine palpation of the neck for lymphadenopathy and masses with palpation of the clavicles. The entire skin surface of the neck should be visualized and palpated while the head is being turned and the skin is being retracted to open the neck creases and folds. The range of motion of the head and neck is evaluated at the same time.

Congenital muscular torticollis at birth is commonly accompanied by a palpable fibrous tumor (fibromatosis colli) in the shortened sternocleidomastoid muscle. Nonmuscular causes of torticollis include tumors of the posterior fossa or cervical spine and cervical spine malformations.

Klippel-Feil syndrome is characterized by a short neck, low posterior hairline, and restricted mobility of the upper spine. Redundant skin or a webbed neck may be seen in trisomy 21 and in Turner and Noonan syndromes. Cystic hygromas are soft fluctuant masses (usually unilateral) that transilluminate. Branchial cleft cysts or sinuses are also found laterally, from the level of the mastoid to the center of the sternocleidomastoid muscle. Thyroglossal duct cysts are found at the midline and high in the neck or under the chin. Laryngeal or tracheal deviation from the midline or enlargement of the thyroid gland warrants a higher level of evaluation. Neuroblastoma may rarely occur with neck mass and signs consistent with Horner syndrome.

Chest Wall

The skin, soft tissue, and bony structures of the thorax should not be ignored when one is assessing cardiorespiratory status. The position of the nipples and the presence of any accessory nipples should be noted. Transient galactorrhea, a result of the lingering effect of maternal hormones, occurs in approximately 5% of term newborns (Madlon-Kay, 1986). Variations in the shape of the xiphoid process are common (a prominent or bifid xiphoid is a benign finding that is less pronounced over time). A mildly depressed sternum (pectus excavatum) or a protuberant one (pectus carinatum) may be of no clinical consequence but should be noted. A small, bell-shaped chest in a newborn with respiratory distress may reflect lung hypoplasia or a disorder of skeletal growth. An increase in the anterior-posterior diameter of the chest (barrel chest) may reflect an increase in the intrathoracic volume caused by air trapping from meconium aspiration or pneumothorax. Crepitus may be felt at the site of a fractured clavicle or rib. Crepitus can also be caused by dissection of air into the subcutaneous tissue from a pneumothorax or pneumomediastinum, but this is an unlikely occurrence in an asymptomatic newborn.

Lungs and Respiration

The respiratory examination begins with observation of the color of the skin and mucous membranes, respiratory rate, breathing pattern, and work of breathing. Respiratory problems are unlikely to be found in a newborn who is centrally pink and breathing comfortably at a normal rate.

In the normal newborn, the abdomen expands smoothly with each contraction of the diaphragm, while the chest moves inward slightly.

The respiratory rate of the newborn is highly variable when the newborn is awake and changes with activity such as feeding and crying. Tachypnea during sleep is more clearly associated with respiratory problems than tachypnea when awake. During an examination the respiratory rate should be determined if tachypnea or hypopnea is evident. Because short pauses and brief periods of rapid breathing are common in normal newborns, accurate measurement of the respiratory rate requires at least a 60-second assessment, preferably when the newborn is asleep or at least not crying. During crying the quality and vigor of vocalization are assessed, and the newborn is observed for changes in color and perfusion. Central cyanosis that *appears* during crying may indicate cardiac or respiratory disease and requires further evaluation. Cyanosis that *resolves* during crying may be due to choanal atresia/stenosis, apnea, or hypoventilation.

The classic signs of neonatal respiratory distress are nasal flaring, grunting, and retractions. Nasal flaring and mild grunting are common in the immediate postnatal period but should resolve within 15–20 minutes after birth. Increasing respiratory distress caused by decreasing lung compliance is typically characterized by a progression in severity of these classic symptoms. The respiratory rate generally decreases as the work or effort of breathing increases, as indicated by the development of grunting and increasing retractions. When respiratory distress is mild, intermittent grunting at a slower respiratory rate may alternate with periods of mild tachypnea. As grunting worsens, the expiratory phase becomes more prolonged. The length of the grunt, rather than its loudness, correlates with the severity of distress. Intermittent mild grunting can be misinterpreted by parents as crying or singing. The rhythm of grunting and its occurrence at the end of expiration are key features that help distinguish grunting from other vocalizations. Retractions require a forceful inspiratory effort and decreased lung compliance, and they may be absent or less prominent than expected in a newborn with neuromuscular depression.

Nasal congestion, airway obstruction, and airway secretions can produce sounds that are audible without a stethoscope. Noisy or congested nasal breathing and intermittent sneezing not associated with upper respiratory tract infection are common in the first few days after birth. A hoarse cry suggests an abnormality affecting the vocal cords. Because intubation of vigorous newborns born through meconium-stained amniotic fluid is no longer routine (Halliday and Sweet, 2001), hoarseness or stridor caused by vocal cord trauma in healthy term newborns has become less common. Inspiratory stridor is due to narrowing or partial obstruction of the upper airway. The presence and loudness of stridor depend on respiratory effort as well as the extent of airway narrowing, so stridor typically worsens with forceful inspiration during crying. Stridor during crying in a newborn with no respiratory distress when quiet is often due to tracheolaryngomalacia (usually benign). Stridor that is present during quiet breathing or present throughout inspiration and expiration suggests the presence of a more significant airway obstruction that requires further evaluation.

A brief chest auscultation of the newborn who is observed to be centrally pink and breathing comfortably in room air is usually sufficient to ensure that breath sounds are clear and that air entry is adequate and equal bilaterally. Breath sounds are not well localized in the newborn, and the newborn might not remain quiet for long, so delineating the quality of breath sounds is usually more helpful than attempting to compare multiple sites. Detection of

abnormal sounds such as crackles, wheezes, or rhonchi requires further assessment. If a more detailed examination is indicated, one should auscultate over the four major quadrants anteriorly, on both sides, and on the upper and lower back bilaterally. Diaphragmatic hernia presenting in the neonatal period usually causes significant respiratory distress. Rarely, a small diaphragmatic hernia is detected by the presence of bowel sounds in the chest of an asymptomatic newborn. Spontaneous cough is abnormal in newborns and is most commonly caused by infection or aspiration.

Although rarely done, percussion of the chest can be useful for estimating the position of the upper margin of the liver. Percussion can also be used to detect a large pleural effusion or lung consolidation, but newborns with these conditions will have other signs of respiratory distress, so the diagnosis will rely on imaging studies and not the physical examination. Transillumination can be useful for supporting a rapid diagnosis of pneumothorax in a distressed newborn, but it is not reliable for detecting a small pneumothorax that produces minimal symptoms.

Respiratory signs are sensitive but nonspecific indicators of illness in the newborn. Alterations in respiration (including apnea) can accompany illness of many different causes. Common causes of subtle or mild respiratory distress detected in routine evaluation include retained fetal lung fluid (transient tachypnea of the newborn), spontaneous pneumothorax, neonatal sepsis, pneumonia, meconium or amniotic fluid aspiration, and congenital heart disease. Any newborn with respiratory distress should be transferred to a NICU or observation nursery for further evaluation, monitoring, and treatment.

Cardiovascular System

The cardiovascular system evaluation has two major goals:

1. Assess the current status of the circulation.
2. Detect signs of congenital heart disease, particularly the critical, ductal-dependent forms that can produce rapid clinical deterioration in the newborn period.

Although detection of heart disease is important, abnormal circulatory findings in the newborn are more often secondary to other problems, including sepsis, hypovolemia, anemia, and hypoglycemia. The cardiovascular system undergoes marked changes after birth involving the transition to air breathing, the progressive decrease in pulmonary vascular resistance, and the closure of the ductus arteriosus. These changes affect the physical examination of healthy newborns and those with congenital heart disease. Timing after birth is always an important consideration in the interpretation of the examination.

The cardiovascular system examination also requires attention be paid to the newborn's general behavior and activity, respiratory signs, color of the oral mucosa, and temperature, color, and perfusion of all body regions. These features will usually be inspected at different times during the course of the examination, but they should be reevaluated with the heart and chest examination if cardiovascular abnormalities are suspected.

Pulse assessment is as follows:

1. Rate. The pulse rate of the well newborn at rest averages 120–130 beats per minute, with high variability. Transient sinus tachycardia during vigorous crying is common, but persistent tachycardia (≥ 160 –180 beats per minute) requires further investigation. A low resting heart rate during sleep (80–100 beats per minute) is common in healthy, hemodynamically stable term newborns.
2. Rhythm. Isolated premature beats occasionally occur in otherwise healthy newborns; these are typically benign.

3. Character. Pulses in a normal newborn can be challenging to palpate (particularly femoral) and are easily obliterated with pressure. “Normal pulses” receive a grade of 2 on the traditional 0–4 scale. If a decrease or delay of the femoral relative to the brachial pulses is detected, measurement of the blood pressure in all four extremities may reveal a gradient in the blood pressure caused by an aortic coarctation. If the ductus arteriosus remains patent, normal pulses and four-limb blood pressures do not rule out a coarctation. Bounding pulses may be palpated with a patent ductus arteriosus once pulmonary vascular resistance has dropped enough to allow significant left-to-right shunting. Uniformly weak pulses suggest a low output state, usually accompanied by signs of poor perfusion.

The precordium is examined by inspection, palpation, and auscultation. A precordial impulse can be visible in normal newborns, especially during activity, but visible prominence of the precordial area plus a palpably increased cardiac impulse suggests cardiomegaly or a hyperdynamic state. Displacement of the cardiac impulse to the right may tip the pediatrician to the presence of dextrocardia or a shift in the mediastinum. Thrills are rarely palpable in the newborn.

Most heart sounds and murmurs auscultated in the newborn are relatively high pitched, so the diaphragm of the stethoscope is usually used initially, and the bell can be used for further evaluation of low-pitched sounds, if needed:

1. S1 is produced by closure of the mitral and tricuspid valves, usually single in newborns, and best heard in the precordial area.
2. S2 is produced by closure of the aortic and pulmonary valves, usually best heard at the left upper sternal border. With focused attention, slight splitting of the second sound and its variation with respiration can be appreciated.
3. S3 and S4 are abnormal in the newborn.
4. Systolic ejection clicks may be heard in some normal newborns in the first several hours after birth, but ejection clicks are abnormal after this period (Johnson, 1990).

The timing, location, intensity, radiation, quality, and pitch are important characteristics of heart murmurs that can help distinguish physiologic from pathologic murmurs. With repeated examination, physiologic heart murmurs may be detected in as many as 60% of newborns during the first 48 hours (Johnson, 1990). These murmurs are most commonly systolic ejection murmurs that are transient and soft (grade I or II). They are usually attributed to flow through a closing ductus arteriosus or to increasing flow across the pulmonary valve as pulmonary vascular resistance drops. Vibratory systolic murmurs resembling Still murmur can be heard in some newborns. A murmur detected on a routine newborn examination that is not clearly physiologic needs further evaluation.

Detection of a suspicious murmur is the most common reason for further evaluation in an otherwise asymptomatic newborn. However, absence of a murmur does not rule out congenital heart disease (e.g., transposition of the great arteries and atrioventricular canal defect). A decrease or loss of a murmur can be an ominous sign that accompanies clinical deterioration associated with ductal closure in a newborn with ductal-dependent pulmonary or systemic blood flow.

Pathologic murmurs detected in the first few hours after birth are usually caused by obstruction of ventricular outflow such as aortic stenosis or pulmonic stenosis. They are crescendo-decrescendo murmurs (grade II or III). This type of murmur may also be caused by subaortic stenosis associated with hypertrophic cardiomyopathy in a macrosomic newborn of a diabetic mother. Murmurs associated with defects that produce left-to-right shunting usually appear

after a few days, when the pulmonary vascular resistance has dropped sufficiently. Pansystolic murmurs (which include and obscure the first heart sound) that are heard soon after birth are most commonly caused by atrioventricular valve insufficiency, whereas left-to-right shunting through a ventricular septal defect produces a pansystolic murmur that typically appears only after 1–2 days. Diastolic murmurs are rare in newborns. A continuous murmur in a newborn usually represents an aortopulmonary communication or an arteriovenous fistula. The location of an extrathoracic arteriovenous fistula may be revealed by auscultation of a bruit, most commonly in the head or liver.

Abdomen

The abdominal examination begins with observation of the configuration, fullness, and movement with respiration of the abdominal wall. Major abdominal wall abnormalities such as omphalocele, gastroschisis, prune belly syndrome, and bladder extrophy will be obvious on initial inspection in the delivery room and may be diagnosed prenatally. A small omphalocele may produce only a slight widening of the umbilicus and proximal part of the umbilical cord (Fig. 25.18). If such an omphalocele is not detected postnatally before the umbilical cord is clamped and cut, the intestine within it may be damaged. Counting of the umbilical vessels is best done in the delivery room on the freshly cut cord.

The abdomen of the newborn ranges from flat to moderately protuberant, with substantial variation depending on feeding and the passage of gas and meconium. A markedly distended abdomen suggests the possibility of significant ascites, a large mass, or an intestinal obstruction. A proximal obstruction (e.g., esophageal or duodenal atresia) does not cause abdominal distention. A sunken or scaphoid abdomen may be seen in the newborn with respiratory distress caused by a diaphragmatic hernia.

The umbilicus should be inspected for meconium staining, signs of infection, visible discharge of urine caused by a patent urachus, and the rare occurrence of pallor and edema. At 1–2 days after birth, slight redness of the periumbilical skin is common, because of irritation from the cord clamp, and needs to be distinguished from an omphalitis or cellulitis. Bowel sounds should be auscultated before one proceeds to palpate the abdomen if the newborn is asleep or resting quietly.

• **Fig. 25.18** A small omphalocele that could be injured if the cord were to be clamped too close to its insertion. (From Rudolph AJ. *Atlas of the Newborn*. Vol 4. Hamilton, Ontario, Canada: BC Decker; 1997:109.)

Palpation should initially be gentle and superficial, to detect any signs of tenderness and the presence of an enlarged liver or spleen. Tenderness must be distinguished from the tendency of the newborn to stiffen the abdominal muscles in reaction to the touch of the examiner's fingers, which are usually colder than the newborn's skin. If the examiner's fingers remain in gentle contact within the same spot, the temperature difference quickly dissipates, and the baby will usually relax and allow the examiner to proceed without struggle. In the healthy newborn, the liver edge may be at or slightly above the right costal margin or palpable 1–2 cm below it. The spleen is rarely palpable unless it is enlarged. Gentle palpation of the lower abdomen can detect an enlarged bladder, which is the most common cause of a midline abdominal mass in newborns. Deep palpation to detect small masses or enlargement of the kidneys is most easily done soon after birth, before significant feeding, and when the newborn is quiet. However, a satisfactory examination can be done even in a crying newborn by one keeping the fingers in position and gradually increasing the depth of palpation each time the newborn briefly relaxes the abdominal muscles while taking a breath between cries. It is helpful to support the flank with one hand while palpating the abdomen to detect the kidney with the other or to palpate the abdomen with the thumb while supporting the flank with fingers of the same hand.

Percussion of the abdomen is not particularly helpful in routine examination, but it can sometimes help to define the boundaries of an enlarged liver or bladder.

Genitalia and Perineum

Brief inspection after delivery is usually sufficient to identify the newborn as male or female. (Evaluation and management of the newborn with ambiguous genitalia are discussed in detail in Chapter 97.) In both male and female newborns, a soft swelling or bulge in the inguinal area may be due to an inguinal hernia. The bulge typically appears or increases in size during crying and is easily reduced with gentle pressure when the newborn relaxes.

The perineum is inspected to locate the anus and assess the tone of the anal sphincter. Absence of a normal anal opening should be detected as part of the initial evaluation in the delivery room. However, external observation of an apparently normal anus does not guarantee internal patency of the anus. That is best confirmed by the normal passage of meconium.

The genitalia are mainly examined by inspection, supplemented by palpation, with the newborn in a supine, frog-leg position.

In the male newborn the foreskin normally covers the entire head of the penis, which is adherent to the glans. The urethral opening is usually hidden by the foreskin and need not be visualized if the foreskin is intact. The foreskin is typically incomplete if hypospadias is present, which allows the abnormal position of the urethral opening to be identified easily.

Congenital chordee, a ventral angulation of the head of the penis, may accompany hypospadias or occur in isolation. Chordee can be missed unless the examiner straightens the penis by gently retracting the skin along the shaft toward the base of the penis. In newborns who have a generous pad of subcutaneous fat at the base of the penis, this maneuver also helps to avoid a false impression that the penis is short.

Dribbling of urine or a weak stream is suspicious of bladder dysfunction or urethral obstruction.

The scrotal sac and inguinal areas are palpated to locate the testes and assess their size. Scrotal rugae usually appear at approximately 36 weeks' gestation and cover the entire scrotum at term. Enlargement of the scrotal sac is most commonly caused by a

hydrocele. Transillumination can help to distinguish a hydrocele from swelling because of congenital testicular torsion or other masses. Bowel sounds may be audible in a scrotum enlarged by an inguinal hernia.

In the female newborn the examiner must gently retract the labia majora laterally to allow full visualization. The sizes and positions of the labia minora, clitoris, urethra, and vaginal opening should be noted. Relative prominence of the labia minora is normal in preterm newborns.

Partial labial fusion and an increase in the size of the clitoris may represent virilization caused by congenital adrenal hyperplasia or related endocrine abnormalities. The posterior fourchette should be at least 1 cm from the anal opening.

Enlargement of the uterus because of hydrometrocolpos may produce a protruding perineal mass. Vaginal tags and mucoid vaginal discharge are common at birth, resulting from exposure to maternal estrogen. A slightly bloody vaginal discharge (pseudomenses) caused by hormonal withdrawal is common in healthy female newborns during the first week after birth.

Back

The back is inspected for asymmetry or abnormal positioning of the shoulders, ribs, and hips. The spine is inspected for straightness and palpated for the integrity and alignment of the posterior spinous processes. Major neural tube defects and large masses such as a large sacrocccygeal teratoma will often be detected prenatally or will be obvious on initial inspection in the delivery room. In the routine examination, the lumbosacral area should be inspected carefully for the presence of deep or unusual dimpling of the skin over the sacrum, for sinus tracts, for unusual tufts of hair, and for small masses such as a lipoma or hemangioma. Any of these findings may be associated with spina bifida occulta or tethering of the spinal cord.

Musculoskeletal System

The newborn's posture, muscle mass, and movements should be observed. Any localized swelling or tenderness should be noted. Major limb or skeletal malformations will usually be appreciated on initial inspection in the delivery room, but minor anomalies such as supernumerary digits, syndactyly, or nail hypoplasia can be missed. Limited movement of an extremity can be caused by trauma (most commonly a fractured humerus or clavicle) or by an intrinsic abnormality of the joint or limb. Although they generally require no treatment, fractures of the clavicle are sufficiently common that the clavicles should be specifically examined in every newborn. Crepitus and tenderness at the site of a clavicle fracture may be more easily detected if the examiner palpates a clavicle with one hand while using the other to elevate and rotate the ipsilateral shoulder.

Deformations of the extremities caused by in utero positioning are not always easy to distinguish from malformations on an initial examination. Mild inward bowing of the lower legs and feet (genu varum) is common in newborns. Congenital talipes equinovarus (club foot) is unlikely if an inward-turning foot can be brought easily to a neutral position. The angulation of the foot can be expected to normalize spontaneously.

Hips. Assessment for developmental dysplasia of the hip (DDH) is an important component of the examination for all newborns as the incidence is estimated at approximately 1 in 1000 live births. Risk factors for DDH include a family history, breech presentation in the third trimester, female sex, abnormal hip examination at birth, and incorrect lower extremity swaddling (Mulpuri et al.,

2015; Shaw and Segal, 2016) DDH may not be present at birth. Therefore surveillance for DDH should continue during infancy until the child is walking with the goal of preventing late DDH presentation (after 6 months of age).

The newborn hip examination begins with general inspection of the newborn. It includes attention to the resting posture and spontaneous movements. Any asymmetry or unusual positioning of the legs should be noted. Asymmetric gluteal or femoral skin folds may be signs of unilateral hip dislocation. In older children, a unilateral dislocation may also produce an apparent inequality of leg length, seen either with the legs in extension (Thomas sign) or with the feet flat on the bed and the knees bent (Galeazzi sign). A restricted range of motion, particularly abduction, is a clue that may detect either unilateral or bilateral dislocations.

The examiner may then proceed to performing the Barlow and Ortolani maneuvers. It is essential that *each hip is examined separately*. Minimal force should be used in performing either maneuver. The dislocation of the femoral head during a Barlow maneuver or its relocation during an Ortolani maneuver produces what is termed a clunk. The key element defining the *clunk* is a distinct sensation of abrupt movement of the femoral head as it passes over the rim of acetabulum and drops into or out of the socket. A dislocated or dislocatable hip has the distinctive clunk, whereas a subluxable hip is characterized by a feeling of looseness or sliding without a distinct clunk (Committee on Quality Improvement, 2009). Both maneuvers are performed with the newborn supine, starting with the legs held in neutral rotation and the hips flexed to 90 degrees but not more.

The Ortolani maneuver is the most important test for determining hip dislocation in a newborn. For this maneuver, the index and middle fingers of the examiner's hand are placed along the greater trochanter, with the thumb placed along the inner thigh near the knee. The other hand stabilizes the pelvis. The examiner gently abducts the hip by rotating the thumb outward while lifting the hip anteriorly with the fingers. A distinct sensation of movement is felt when a posteriorly dislocated hip relocates during abduction (visit <http://www2.aap.org/sections/ortho/> and scroll down to the Barlow–Ortolani video).

A positive Ortolani maneuver test finding prompts referral to an orthopedist. An ultrasound examination is not necessarily required/needed. Newborns with positive Barlow test results at either the newborn examination or the 2-week examination may have spontaneous resolution. However, these newborns should have sequential follow-up examinations as part of DDH surveillance (Shaw and Segal, 2016). For newborns with equivocal examination findings, the pediatrician should remain alert for the presence of other warning signs such as asymmetric creases, limited abduction, and apparent or true leg length discrepancies. Controversy remains regarding when additional diagnostic testing should be performed. Selective ultrasound screening may be performed in any newborn (male or female) if there were concerning findings on the initial newborn examination and/or in patients with significant risk factors (e.g., family history, breech presentation at birth, improper swaddling) because an ultrasound examination after 6 weeks of age and/or radiographs at 4–6 months of age may assist in detecting clinically silent DDH in the “high-risk” infant (Shaw and Segal, 2016).

Neurologic Examination

The neurologic system is assessed during the course of the general newborn examination and by the examiner performing some specific maneuvers to elicit neonatal reflexes. Because the healthy newborn's

responses vary with the state of alertness, and tolerance for prolonged examination is limited; elicitation of a perfect response to each maneuver should not be expected.

The newborn screening examination includes assessment of the newborn's alertness, spontaneous activity, posture, muscle tone and strength, head control, and responses to manipulation and handling. When an examination raises doubts, repeating selected parts at a later time may be more helpful in clarifying findings if the patient is otherwise stable.

The typical newborn will be alert for several hours after delivery but frequently becomes "sleepy" and uninterested in feeding for the remainder of the first 24 hours. If the newborn continues to be easily aroused and the examination findings remain otherwise normal, feeding will likely improve on the second day.

Alertness, tone, and activity are important components of the entire examination:

1. Normal newborns are easily awakened from sleep and remain alert through the remainder of the routine examination, shifting among states of quiet alertness, active alertness, and crying. The cry is vigorous when the newborn is upset, but a newborn should be able to self-console or should be consoled with holding, sucking, or feeding.
2. Diminished alertness, tone, or spontaneous activity are sensitive but nonspecific indicators of illness (e.g., neonatal sepsis, inborn errors of metabolism) rather than suggestive of a neurologic abnormality. A newborn who is stuporous or difficult to arouse is abnormal and needs further evaluation, as does a newborn who is unusually irritable or inconsolable.
3. Decreased tone or alertness occurring more than 24 hours after birth in a previously vigorous newborn is abnormal and requires prompt investigation for sepsis or other problems, including inborn errors of metabolism that can cause progressive neurologic signs because of accumulating toxic metabolites.

Sensory assessment relies on observation of the strength and quality of the newborn's movements in response to handling during the examination and to specific local stimulation, such as the elicitation of the palmar and plantar grasp reflexes, rooting reflex, and sucking reflex. This is obviously necessary because the newborn cannot verbally answer questions or voluntarily respond to commands.

Vision assessment is limited to observation of the following:

1. Pupillary constriction and blinking response to light (subcortical responses)
2. Newborn's visual attentiveness. A healthy term newborn is expected to visually fixate on and follow the examiner's face, but this can take considerable time to elicit.

Hearing assessment can be evaluated behaviorally by observation of the newborn's responses to the ringing of a bell or other sounds. However, this detects only profound, bilateral hearing loss, and it has been effectively replaced in the routine newborn examination by automated hearing tests ([American Academy of Pediatrics, 2007](#); [US Preventive Services Task Force, 2008](#)).

Motor function assessment relies on the observation of the newborn's posture and spontaneous movements, observation of the newborn's general responses to stimulation and handling, and the elicitation of specific reflexes. The scarf sign, forearm recoil, square window of the wrist, heel-to-ear maneuver, and popliteal angle are measures of tone and flexibility commonly scored in the GA assessment ([Dubowitz et al., 1970](#); [Ballard et al., 1991](#)).

In normal resting posture the elbows, hips, and knees are strongly flexed in the healthy term newborn.

Active tone and strength of upper extremity muscle groups are routinely assessed by elicitation of the palmar grasp and by arm traction during the pull-to-sit maneuver. Active tone and strength of lower extremity muscle groups are assessed during the general examination of the hips and feet and by testing for the supporting reaction, stepping reflex, Babinski reflex, and ankle clonus.

Neck flexors may be evaluated during the standard pull-to-sit maneuver or by the lifting of the shoulders to pull the baby to a sitting position. The neck *extensors* can be evaluated by the tilting of the newborn forward from a sitting position or can be evaluated along with truncal tone by the newborn being suspended in a prone position with the examiner's hand under the chest (ventral suspension maneuver).

During the examination, one should note any asymmetry and pay attention to qualitative characteristics such as the relative smoothness versus jerkiness or tremulousness of movement. Unusual jitteriness may be a sign of hypoglycemia or hypocalcemia, especially in newborns of diabetic mothers, newborns who are small or large for their GA, or newborns who were exposed to opiates or other drugs in utero and are experiencing withdrawal.

Passive restraint of an extremity should inhibit jittery movements but may not stop rhythmic contractions of seizure activity. The signs of neonatal seizures include:

1. Clonic movements
2. Tonic posturing
3. Repetitive stereotypical movements of the face or extremities
4. Tonic horizontal eye deviation or nystagmoid jerking
5. Staring or blinking
6. Apnea (distinct from apnea of prematurity, particularly for a term newborn)
7. Unexplained changes in heart rate or blood pressure

It is uncommon to observe an actual seizure during a routine newborn examination, but the pediatrician may be called to evaluate a newborn with a report of unusual movements.

In the otherwise healthy newborn who is fully alert and responsive, jerky or abrupt movements that are evoked by stimulation (e.g., startles), that can be suppressed by passive restraint (e.g., jitteriness), and that are not accompanied by autonomic changes or changes in alertness are unlikely to be seizures. Transient episodes of disconjugate gaze are also not unusual in normal newborns, particularly when the newborn is entering or awakening from sleep.

Neonatal Reflexes. The neonatal or primitive reflexes frequently tested during routine examination of the newborn include the Moro reflex, the asymmetric tonic neck reflex, truncal incurvation (Galant reflex), the palmar and plantar grasp reflexes, the Babinski reflex, and the placing and stepping reflexes.

The Moro reflex can be elicited following the pull-to-sit maneuver, by the lowering of the newborn until there is only a slight space between the neck and bed, and then allowing the newborn to fall back suddenly. Alternatively, the Moro reflex can be elicited by the "drop" method: the examiner lifts the baby completely off the bed, supporting the head and trunk with both hands and keeping the baby supine, and then rapidly lowers the baby by approximately 4–8 inches. The complete Moro reflex involves a quick bilateral abduction of the arms and extension of the forearms with full opening of the hands, followed by smoother and slower return of the hands toward the midline, with curling of the fingers.

The startle reflex is similar to the Moro reflex, but without full extension or hand opening, and may occur spontaneously or may be evoked by a sudden noise or movement.

The asymmetric tonic neck reflex demonstrates how neck position affects the tone of the extremities. This should be kept in mind during observation of the newborn's spontaneous movements, because it can cause a false impression of asymmetry if the position of the neck is not taken into account. To test the asymmetric tonic neck reflex, turn the newborn's head 90 degrees to one side for 15 seconds, keeping the newborn lying on the back with the shoulders horizontal. In a complete response, the ipsilateral arm and leg will extend and the contralateral arm and leg will flex, producing the "fencing" posture. The test is then repeated with the head turned to the other side. Observation of the complete response is reassuring, but its absence is not necessarily abnormal (partial and unidirectional responses are common too). However, an unusually sustained or exaggerated response is abnormal.

The truncal incurvation reflex is elicited with the newborn held in ventral suspension by the examiner stroking lightly down the back on one side and then the other. The normal response is for the newborn to curve the spine strongly, concave toward the stimulated side.

The supporting, placing, and stepping reflexes are elicited with the newborn held upright. The supporting reaction is elicited by the examiner lowering the newborn vertically until both feet touch the surface of the bed or table. A positive response, usually seen after a slight delay, is partial extension at the hips and knees, as though the newborn is attempting to stand and support his or her weight. The stepping reaction is tested by the examiner lowering the newborn so that one foot touches the surface, with the newborn tilted slightly forward. The newborn should flex that leg and extend the other, as though taking a step. The placing reaction is elicited by the examiner lifting the newborn to bring the dorsum of one foot in contact with the underside of a table or bassinet edge. In a positive response, the newborn lifts the foot up and places it on the top surface.

The Babinski reflex consists of dorsal flexion of the big toe and spreading of the other toes in response to stroking of the foot laterally (normally observed in newborns).

Firm pressure on the sole of the foot elicits the plantar reflex.

The deep tendon reflexes are usually not elicited during routine examination of the well newborn, but they are helpful as part of a more complete examination if neurologic abnormalities are suspected. The pectoralis, biceps, brachioradialis, thigh adductor, crossed adductor, knee jerk, and ankle jerk reflexes are the most readily elicited (Volpe, 2008). Ankle clonus may be elicited by quick dorsiflexion of the foot, which in a healthy term newborn should produce no more than approximately five beats of alternating extension and flexion with rapidly decaying intensity.

Brachial Plexus Injury. Although not common, brachial plexus injury is one of the more frequent neurologic abnormalities found in the otherwise healthy newborn, occurring in about 0.5–2 per 1000 live births. Often there is a history of difficult delivery because of shoulder dystocia. Brachial plexus injury can occur in isolation or in conjunction with fractures of the clavicle or humerus. Typical findings in Erb palsy are an inability to abduct and externally rotate the shoulder, flex the elbow, and supinate the forearm because of injury to C5–C6 (Volpe, 2008). If C7 is involved, wrist and finger extension are also weak (Fig. 25.19). A distal brachial plexus injury involving C8–T1 causes weakness of wrist and finger flexion.

Cranial Nerves. Observation and maneuvers during the routine examination provide at least partial assessment of all the CNs (Volpe, 2008) except for the olfactory nerve (CN I), which is not routinely tested. The corneal reflex can be tested by the examiner

• **Fig. 25.19** Hand and arm position in a newborn with Erb palsy involving C5, C6, and C7. (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:450.)

touching the cornea with a wisp of sterile cotton, but this is also not part of the routine newborn examination. Similarly, the masseter or jaw-jerk reflex can be elicited by the examiner placing the forefinger of one hand on the newborn's relaxed chin and tapping it with the forefinger of the other hand, but this is not routinely done either. Lastly, taste, mediated by CN VII (anterior two-thirds of the tongue) and CN IX (posterior third), is not evaluated during the routine examination.

Visual attentiveness, the ability to fix and follow, eyelid closing in response to light, and the pupillary light reflex require the optic nerve (CN II). The pupillary light reflex also tests the oculomotor nerve (CN III). CNs III, IV, and VI control extraocular movements.

Elicitation of rooting or a facial grimace in response to touching the face tests the sensory portion of the trigeminal nerve (CN V). The motor portion of CN V controls the muscles of mastication, which are involved in the jaw-closing phase of the suck and are assessed during elicitation of the suck when the newborn bites down on the examiner's finger.

Vertical gaze is difficult to assess in neonates, but horizontal gaze in both directions can usually be verified by observation of spontaneous eye movements or by the rotation test. The examiner performs the rotation test by turning in place while holding the newborn upright and supporting the back of the head.

If vestibular functions are intact, the newborn will turn the head in the direction of rotation or, if the head is restrained, turn the eyes in that direction. The doll's eye maneuver may also be used to assess CN VIII. The auditory portion of CN VIII is best assessed with use of brainstem auditory evoked responses, rather than behavioral responses to auditory stimulation.

CNs V, VII, IX, X, and XII are all involved in normal sucking and swallowing.

• **Fig. 25.20** Unilateral Facial Weakness in Two Newborns. There is mild facial asymmetry with flattening of the nasolabial folds at rest (A, C) and more obvious asymmetries of the grimace and eye closing during crying (B, D). The weakness is on the newborn's left side in (A) and (B) and on the newborn's right side in (C) and (D). (From Fletcher MA. *Physical Diagnosis in Neonatology*. Philadelphia: Lippincott-Raven; 1998:457.)

The facial nerve (CN VII) is required for pursing of the lips in sucking, as well as normal facial expression and tone. In utero positioning or forceps injuries that compress the facial nerve are common causes of unilateral facial weakness in the newborn period (Fig. 25.20).

CNs IX and X are needed for normal swallowing and the gag reflex. CN XII is involved in the milking action of the tongue during sucking and swallowing. CN XI is involved with sternocleidomastoid function and is assessed by evaluation of head flexion and lateral rotation. Because head control is often poor in normal newborns, it can be difficult to detect an abnormality unless it is unilateral. However, an asymmetric abnormality of a sternocleidomastoid is caused more commonly by torticollis than dysfunction of CN XI.

Newborn Nursery Care

JAMES A. TAYLOR, JEFFREY A. WRIGHT, AND DAVID WOODRUM

KEY POINTS

- Interventions for newborns during the newborn nursery stay should be limited to those for which the evidence of benefit is clear.
- The short-term and long-term benefits of breastfeeding are clear. The effects on breastfeeding rates from interventions such as formula supplementation, frenotomy, and restriction of pacifiers are controversial.
- Comprehensive guidelines for management of common newborn conditions such as jaundice, risk of sepsis, and hypoglycemia are available. However, whether use of these guidelines improves outcomes is unclear.
- Online aids are available to clinicians to help guide individualized management of jaundice and weight loss in both breastfed and bottlefed newborns.
- With the implementation of universal maternal screening for group B streptococcus and the use of intrapartum antibiotic prophylaxis, rates of sepsis in term newborns have fallen significantly. Online aids are available to guide clinicians in assessing the risk of sepsis.
- Prenatal ultrasonography can diagnose multiple newborn conditions early. However, the natural history of many common ultrasound findings is variable, and the findings may, or may not, represent markers for serious disease.
- Pulse oximetry screening for critical congenital heart disease is recommended for healthy newborns. False-positive rates are low, but there is a substantial false-negative rate.

Two central paradoxes underlie the care of normal newborns. First, although birth is, almost by definition, the most natural of all human processes, until very recently the newborn mortality rate has been extraordinarily high. The second paradox in providing newborn care is that neonates are both the healthiest and the most vulnerable patients in medicine. Recent medical history is replete with examples of the pendulum swinging too far in each direction around these paradoxes. The promotion of scheduled feeding using infant formulas rather than breastfeeding is an example of the overmedicalization of neonatal care. Conversely, recent resistance to treatments that prevent uncommon, but disastrous, conditions represent a denial of the benefits provided by medical care.

Thus optimal care of a normal neonate is an attempt to balance these competing forces. Systems of care should be designed to support the concept that newborns are extraordinarily healthy and require little intervention beyond promotion of breastfeeding. Those interventions for which there is clear evidence that the benefits outweigh the risk should be provided as unobtrusively as possible. Simultaneously, while promoting “natural” care for these newborns,

healthcare providers need to be vigilant for the early identification of neonates who are at risk of conditions such as dehydration, sepsis, and severe hyperbilirubinemia.

The goal of this chapter is to provide an evidence base for the promotion of normal newborn care by parents, the rationale for monitoring term neonates for various conditions, a risk–benefit analysis of common treatments, and the significance of common prenatal and postnatal findings. Rather than providing a comprehensive prescription on how to care for these newborns, we hope that the reader will integrate the information provided in this chapter with expert opinion and his or her own clinical experience to determine the proper management of normal newborns.

Initial Assessment

The timing of the initial assessment of a term newborn is dependent on the condition of the newborn and parental preference. In most instances a healthcare professional who is present at the birth will make a general appraisal of the newborn and alert the child’s provider if there is an acute problem necessitating an immediate evaluation. Usually the neonate will be healthy, and the assessment can be timed so as not to interfere with breastfeeding, bonding with the family, and routine care.

Before a well newborn is examined, the mother’s medical history should be reviewed to identify issues that could affect the care or prognosis of the newborn. For example, a history of diabetes in the mother would lead to glucose testing in the neonate. Maternal drug use should be assessed for possible teratogenic effects, possibility of symptoms of withdrawal in the newborn, and compatibility with breastfeeding. It is important to review the pregnancy history, focusing on estimated gestational age (GA), the results of screening for genetic conditions, and the results of prenatal ultrasound examinations. Perinatal events such as the type of delivery, length of time that membranes were ruptured, and Apgar scores should also be reviewed. Finally, it is critical to review the mother’s social history to ensure that the newborn will be raised in a nurturing environment and to identify high-risk situations for which interventions are needed before, or shortly after, discharge from the newborn nursery.

The results of several laboratory tests commonly performed on pregnant women will determine the need for treatment and/or monitoring during the newborn nursery stay. These include maternal HIV and hepatitis B (HBV) surface antigen status and syphilis testing. The mother’s blood type, Rhesus (Rh) status, and antibody test results are useful in identifying newborns with an increased risk of hyperbilirubinemia. It is important to note the results of testing for maternal colonization with group B streptococcus (GBS)

and the type and timing of antenatal antibiotic prophylaxis in mothers who are GBS positive.

The newborn's weight, length, and head circumference should be measured shortly after birth and plotted on a standardized chart. Although the most common reason for a significant discrepancy between weight, height, and head circumference percentiles is an inaccurate measurement, a valid discrepancy warrants close clinical observation or testing. Glucose testing may be indicated for newborns found to be small or large for their GA. If the estimated GA of the newborn is inconsistent with the growth parameters, then a formal evaluation by a Dubowitz–Ballard GA assessment may be helpful (Ballard et al., 1979).

When a newborn is examined for the first time, the initial focus is directed toward an overall assessment of the child's health. Observation and auscultation of the chest allow detection of an irregular heart rate, murmur, or acute lung condition such as pneumothorax. The heart rate and respiratory rate can be measured. Normal values for heart and respiratory rate in a newborn are 100–160 beats per minute and 35–60 breaths per minute respectively. Evaluation of skin color may be useful for the identification of a neonate with cyanotic congenital heart disease or pulmonary conditions. If uncertainty exists about the presence of cyanosis, oxygen saturation can be quickly measured with a pulse oximeter. The newborn's tone, general posture, and movement should be assessed; abnormalities may be indicative of an acute or chronic central nervous system problem or sepsis.

Routine Testing

Glucose

The fetal blood glucose level is approximately 70% of that of the maternal level. Following birth and separation from its major energy supply, the newborn's glucose level falls, on average, by a factor of two. Over the next several hours, it gradually increases to a level approaching that of older newborns (Fig. 26.1). The critical factors involved in this normal adaptive process include transient inhibition of the newborn's insulin secretion and an increase in levels of the counterregulatory hormones: growth hormone, cortisol, catecholamines, and glucagon (Adamkin, 2015). The effect of this is to promote liver glycogen breakdown, gluconeogenesis, and tissue lipolysis. Clinical scenarios that might indicate the need for early glucose screening and possible therapeutic intervention include:

- Any newborn who demonstrates clinical signs of hypoglycemia (Box 26.1)
- Newborns of diabetic mothers/large for GA newborns
- Newborns demonstrating intrauterine growth retardation
- Premature newborns
- Newborns delivered after in utero and/or intrapartum distress
- Family history of congenital hyperinsulinism

• BOX 26.1 Clinical Signs Compatible With Hypoglycemia

Poor feeding
Lethargy
Hypotonia
Irritability
Tremor
Seizure-like activity
Apnea

- Newborns with midline facial anomalies that might be markers for pituitary deficiency

The treatment approach to confirmed hypoglycemia depends on the glucose level and/or the presence of clinical signs. Newborns with symptomatic hypoglycemia require immediate intervention (Committee on Fetus and Newborn and Adamkin, 2011). However, while it is apparent that severe and symptomatic hypoglycemia result in brain injury leading to developmental and other issues, the effects of less severe and asymptomatic hypoglycemia on the neonatal brain are much less clear (Burns et al., 2008; Rozance and Hay, 2012). Thus there is considerable debate regarding the definition of *hypoglycemia* and an actionable glucose level in this early transition period in asymptomatic newborns. In an attempt to provide a rational and standardized approach, the American Academy of Pediatrics (AAP) published a guideline on neonatal hypoglycemia in 2011 (American Academy of Pediatrics. Committee on Fetus and Newborn and Adamkin, 2011). It is recommended that asymptomatic, at-risk term and late preterm newborns who have glucose levels below 25 mg/dL in the first 4 hours after birth or levels below 35 mg/dL at 4–24 hours of age should receive intravenous glucose. Early feeding and retesting are suggested for those with glucose levels between 25 and 45 mg/dL, depending on age. Whereas a “target” glucose level greater than 45 mg/dL before routine feeds is recommended, the guideline authors acknowledge that there is no clear evidence that this is the appropriate threshold for defining a normal glucose level in newborns (American Academy of Pediatrics. Committee of Fetus and Newborn and Adamkin, 2011).

Following publication of the guideline, two large studies on neonatal hypoglycemia have had somewhat contradictory results.

• **Fig. 26.1** Predicted plasma glucose values during the first week of life in healthy term neonates with birthweight appropriate for their gestational age. Green and orange lines denote upper and lower limits of 95% confidence interval, respectively, around the mean values (blue line). (Modified from Srinivasan G, Pildes RS, Cattamanchi G, Voora S, Lilien LD. Plasma glucose values in normal neonates: a new look. *J Pediatr*. 1986;109:114–117.)

First, among a group of almost 1400 fourth grade children who had universal glucose screening during their birth hospitalizations, those with transient hypoglycemia, defined as a glucose level below 35 mg/dL, below 40 mg/dL, or below 45 mg/dL, were significantly more likely to score below grade level on standardized testing for literacy and mathematics proficiency than those without hypoglycemia. The odds ratios for lack of proficiency related to hypoglycemia ranged from 1.28–2.33, and there was some suggestion of a “dose effect” with severer hypoglycemia leading to worse outcomes (Kaiser et al., 2015). Conversely, in a prospective study of 528 newborns at risk of hypoglycemia, no association between hypoglycemia (defined as a glucose level <47 mg/dL) and developmental assessment at 2 years of age was found (McKinlay et al., 2015). In this study, newborns were managed with a goal of maintaining a glucose level greater than 47 mg/dL; neither the number of hypoglycemia episodes nor the lowest glucose concentration was associated with abnormal development. Further, study participants underwent continuous interstitial glucose monitoring, but the results of this monitoring were not available to the treating clinicians. Nearly 25% of study newborns had undiagnosed and untreated hypoglycemia identified with continuous monitoring, some for several hours. These episodes of unrecognized hypoglycemia were also not associated with developmental delays.

Taken in their entirety, the results of these two large studies suggest that it is “safe” to follow the AAP hypoglycemia guideline; screening and treatment protocols designed to maintain glucose levels greater than 45 mg/dL are associated with good developmental outcomes. It is much less clear if this is the “best” approach. The higher the threshold for defining hypoglycemia, the more testing and treatment there will be in asymptomatic newborns. It is possible that, in the absence of a clear benefit, more screening and more treatment will actually lead to more harm than good (McKinlay and Harding, 2015). In addition, although the rate of hypoglycemia is greater in newborns at risk, at any given time in a typical newborn nursery most newborns with hypoglycemia will be term newborns without any risk factors, simply because there are so many more of these neonates (Kaiser et al., 2015). Thus most hypoglycemia in a newborn nursery goes undiagnosed if screening is limited to those at risk.

Newborn Metabolic Screening

Newborn screening (NBS) for metabolic disorders began in 1962 when 29 states participated in a trial of testing for phenylketonuria (PKU). With the implementation of screening programs, criteria were proposed for determining which conditions should be included in screening programs. It was recommended that only disorders that were important health problems be included in screening programs. The condition should be detectable before the onset of significant symptoms. Importantly, a specific treatment to prevent adverse clinical consequences from the disorder should be available, and the screening program for the condition should be cost effective (Tarini, 2007). On the basis of these criteria, conditions such as congenital hypothyroidism and congenital adrenal hyperplasia were slowly added to NBS tests in many states, and subsequently conditions such as sickle cell disease were added. Although there is no specific treatment for sickle cell disease, there was evidence that the use of an NBS program to identify newborns with the disorder led to early initiation of penicillin treatment, which resulted in fewer deaths from sepsis than when newborns were identified at the onset of symptoms (Vichinsky et al., 1988). Given the demonstrable effectiveness of early identification, sickle cell disease met the criteria for newborn screening.

The advent of tandem mass spectrometry in the 1990s revolutionized newborn metabolic screening. With this technology it is possible to test for a multitude of conditions on a very small sample of blood. In 1995 the average number of conditions included in state-mandated screening programs was 8; by 2005 this had increased to 19, with some states testing for up to 46 conditions. Unfortunately, this increase in NBS has been controversial. Some of the conditions included do not meet the long-established criteria for screening in that there are no known effective treatments, and, in some cases, it is not known whether the targeted condition always leads to disease. In addition, with increasing numbers of tests come increasing numbers of false-positive results, leading to increased parental anxiety and potential for overuse of medical services (Tarini et al., 2006; Berry, 2015).

In an attempt to define a rational list of disorders for which NBS is appropriate, the American College of Medical Genetics used an iterative process to identify 29 “core conditions” that should be included in mandatory screening programs (Watson et al., 2006). Subsequently, federal legislation was passed to facilitate standardization of NBS across the United States. This legislation led to the development of the Recommended Universal Screening Panel, which initially included 29 core disorders. All US states currently provide testing for all of these disorders (Berry, 2015). The recommended screening panel has now been expanded to include 32 core disorders and 26 secondary disorders. In addition to newborn hearing screening and screening for critical congenital heart disease (CCHD), there are nine organic acid, five fatty acid oxidation, six amino acid, two endocrine, three hemoglobin, and four other conditions included in the list of core disorders. Information on the screening program in each state in the United States and on specific disorders can be found at <http://www.babysfirsttest.org>.

The most common disorders included on newborn metabolic screens in the United States are congenital hypothyroidism (1 case per 3000–4000 newborns) and sickle cell disease (Kaye et al., 2006; Hertzberg et al., 2011). The incidence of PKU is approximately 1:15,000 (Serving the family from birth to the medical home, 2000). For many of the core conditions for which screening is now recommended, the incidence rates are in the 1:100,000 to 1:200,000 range (Kaye et al., 2006). For some disorders, the incidence rate is unknown.

Hearing Screening

Newborn hearing screening has become universal in the United States, with more than 97% of newborns screened in 2013. Every state and territory in the United States has now established an early hearing detection and intervention program and is required to provide tracking data. Newborns who do not “pass” the hearing screen in the newborn nursery should be referred for more definitive testing in a timely manner. Ultimately, in 4.8%–10.3% of newborns who do not pass the hearing screen, permanent hearing loss is diagnosed; the current rate of hearing loss in the United States is approximately 1.5 per 1000 newborns screened (Williams et al., 2015; Summary of 2013 National CDC EHDI Data, 2016). Many other countries have adopted or are in the process of adopting universal hearing screening. Experts from the World Health Organization endorsed universal newborn hearing screening in 2009. It is reported that 80% of early childhood hearing loss is congenital and that most cases have genetic origins and/or are a result of cytomegalovirus infection (Declau et al., 2008; Lammens et al., 2013).

There is growing evidence that early intervention with amplification or cochlear implants can improve childhood reading, language,

and communication skills (Vohr et al., 2008; McCann et al., 2009; Ohmori et al., 2015; Stika et al., 2015). These treatments are effective when implemented by 6 months of age, preferably younger. This creates time urgency to verify an initial screen with a test and make referrals to specialists who can provide treatment. This process is particularly challenging in rural areas and in countries with limited access to these services (Bush et al., 2015).

A significant challenge is to avoid labeling a child as abnormal with this screening process. Of the newborns who fail to pass their newborn hearing screen, more than 80% will be found to have normal hearing on follow-up testing (Nelson et al., 2008). Given this false-positive rate, approximately 8–10 newborns with normal hearing will be referred for follow-up testing to identify newborns with hearing loss (Nelson et al., 2008). The risk of labeling a child as possibly abnormal can cause permanent alteration of the parent–child relationship, a condition dubbed *vulnerable child syndrome* (Pearson and Boyce, 2004).

To decrease the risk of false-positive tests and vulnerable child syndrome, it is recommended that the term *refer* be used instead of *fail* when the screen results are being discussed. Babies have an increased “refer” rate when born by cesarean delivery or screened during the first day of life, so it is best to wait until the third or fourth day to screen newborns whenever possible (Lupoli Lda et al., 2013; van Dyk et al., 2015; Xiao et al., 2015). Many nurseries have adopted a two-step process using an automated otoacoustic emissions (OAE) test for the first step followed by a brainstem auditory evoked potential test in those who do not pass the automated OAE test. This process has been shown to decrease the false-positive rate (Papacharalampous et al., 2011; Caluraud et al., 2015). All newborns who are at high risk of early hearing loss should be sent directly for auditory brainstem response (ABR) screening. High-risk factors include premature birth, family history of early childhood or infant hearing loss, craniofacial anomalies or abnormal ear examination findings (includes microtia but not tags), and exposure to aminoglycoside antibiotics.

False-negative screens are also a concern but the rate is low. A screen will be falsely negative in 0%–2% of newborns (Johnson et al., 2005; Cebulla et al., 2014). With use of ABR screening, the false negative rate is lower.

Screening for Critical Congenital Heart Disease

It has been estimated that approximately 25% of newborns with congenital heart disease have “critical” lesions, defined as a lesion requiring surgery and/or cardiac catheterization in the first year of life (Mahle et al., 2009). Overall, CCHD is diagnosed in less than half of newborns prenatally, and 25%–30% are not identified as having CCHD during the birth hospitalization (Peterson et al., 2014). Further, some neonates with lesions that are amenable to surgical intervention who are not identified as having CCHD before discharge from their birth hospitalization may die from their CCHD before a clinical diagnosis is made (Peterson et al., 2014). Because of this, it is now recommended that all newborns be screened with pulse oximetry for CCHD before discharge from their birth hospitalization (Mahle et al., 2012).

Pulse oximetry screening is based on the concept that most, but not all, CCHD lesions lead to hypoxemia in the affected newborn. To minimize false-positive results, pulse oximetry screening should be delayed until newborns are 24 hours or older, if possible. Conversely, since some newborns with CCHD have different oxygen saturation levels when measured preductally or postductally, false negatives results are reduced by screening newborns both in the right hand (preductal) and in a lower extremity (postductal). Newborns with

a measured oxygen saturation level of less than 90% at either site are classified as having a positive screen and should be evaluated by a pediatric cardiologist on an urgent basis. Repeated screening is recommended for newborns with oxygen saturation levels of 90% or greater and less than 95% or with a difference of 3 or more percentage points between the right hand and the lower extremity; if either of these findings persists after three screenings, the screen is considered positive (Kemper et al., 2011).

There were initially concerns that wide-scale implementation of universal pulse oximetry screening would result in a high proportion of false-positive results, leading to unnecessary and expensive evaluations of normal newborns. Thankfully, these concerns have been largely unfounded, with observed false-positive rates of less than 0.5%. However, the sensitivity of pulse oximetry screening is only approximately 77% (Thangaratinam et al., 2012). Sophisticated models have indicated that the number of “true” positives might be approximately matched by the number of false-negative results (Ailes et al., 2015). Given this, a diagnosis of CCHD should be seriously considered in a young infant with signs or symptoms of one of the lesions that screening is designed to identify despite the presence of negative screening results during the birth hospitalization.

Prenatal Ultrasound Screening for Birth Defects

Ultrasound screening for fetal anomalies has become increasingly routine. Major fetal organ system abnormalities can, for the most part, be identified, and the mother can be referred for appropriate fetal and neonatal management. There are, however, a number of ultrasound findings that have a variable natural history, which may or may not be markers for serious conditions and do not always result in a definitive prenatal work-up. These findings often do not fit within the pediatric lexicon. They can present a challenge to the pediatrician when it comes to parent counseling and/or determining management in the neonatal period.

Central Nervous System Findings

Choroid plexus cysts are found in 2%–4% of second trimester fetal ultrasound examinations. They are transient, functionally benign in nature, and generally resolve spontaneously before term. If one or more choroid plexus cysts are found in isolation on prenatal ultrasound examination, no adverse effect on fetal growth and development has been noted. Thus without other risk factors, no further evaluation is needed in an infant with this isolated finding who has had a benign prenatal and a normal postnatal course (Ebrashy et al., 2016). Choroid plexus cysts are believed to be a “soft marker” for aneuploidy (particularly trisomy 18) when associated with other fetal anomalies or with maternal risk factors, such as advanced maternal age. In such situations current recommendations are to begin an appropriate prenatal evaluation, that is, karyotyping (DiPietro et al., 2006; Lopez and Reich, 2006; Sohaey, 2008a).

Agensis of the corpus callosum is reported to occur in 0.3%–0.7% of unselected postnatal populations. Aneuploidies have been reported in 10%–20% of children with this prenatal ultrasound finding. Major organ system abnormalities are reported to occur in up to 60% of such fetuses. Notably, when absence of the corpus callosum is an isolated fetal ultrasound finding, the reported rate of a relatively normal developmental outcome ranges from 50% to 75%. However, well-conducted long-term follow-up studies are lacking. It is recommended that fetal magnetic resonance imaging be considered when one is confronted with this diagnosis since other abnormalities have been identified in more than 50% of such fetal patients. Postnatal management for infants with a

history of agenesis of the corpus callosum on prenatal ultrasound examination should include, at a minimum, close clinical assessment and indicated work-up (Fratelli et al., 2007; Chadie et al., 2008; Winter, 2008; Sotiriadis and Makrydimas, 2012).

Mild, isolated ventriculomegaly is a relatively uncommon fetal ultrasound finding that may be a soft marker for aneuploidy, fetal infection, or other central nervous system abnormalities. As such, it is recommended that serial imaging studies and, in some cases, more extensive work-up be undertaken. In the presence of a benign fetal assessment, most newborns appear to do reasonably well following delivery. It is important to consider close developmental follow-up and serial imaging studies (Leitner et al., 2009; Melchiorre et al., 2009; Devaseelan et al., 2010).

Cardiac Findings

Echogenic cardiac focus is an incidental ultrasound finding in 3%–4% of normal fetuses. Notably, there is an increased incidence (10%–30%) in Asian populations. It is said to be a soft marker for chromosomal abnormalities (trisomy 21 and trisomy 13) when associated with other screening abnormalities. Further work-up may be indicated in high-risk populations. If the physical examination findings for a newborn are normal and there are no other ultrasound findings, no further evaluation is suggested (Borgida et al., 2005; Koklanaris et al., 2005; Ouzounian et al., 2007; Sohaey, 2008b Rodriguez et al., 2013).

Gastrointestinal Findings

Echogenic bowel when noted to be present during a second trimester ultrasound examination and determined to be grade 0 or 1 (i.e., less echogenic than bone) is considered a normal variant with a good prognosis. No special prenatal or postnatal work-up is recommended. Anything of density equal to or greater than that of bone (grade 2 to 3) is abnormal and potentially a marker for cystic fibrosis, trisomy 21, gastrointestinal anomalies, in utero infection, bowel ischemia or bleeding, intrauterine growth restriction, and/or impending in utero demise. Appropriate work-up is indicated (Goetzinger et al., 2011; Ebrashy et al., 2016).

Cholelithiasis is an uncommon third trimester fetal ultrasound finding that needs to be differentiated from hepatic calcification. Cholelithiasis is considered a benign condition requiring no special evaluation or treatment but careful clinical follow-up. An imaging examination at 1 year of age for a child with this prenatal finding may be helpful in documenting expected resolution (Sohaey, 2008d; Triunfo et al., 2013).

Hepatic calcifications are uncommon fetal ultrasound findings. They are often isolated, single and, in a low-risk mother, of no significance. However, when numerous, hepatic calcifications may be markers for fetal aneuploidy, infection, meconium peritonitis, hepatic tumor, or vascular insult. A significant percentage are associated with some form of fetal disease. Neonatal management depends on the prenatal work-up and the clinical presentation in the newborn period (Simchen et al., 2002; Pata et al., 2012).

Urinary Tract Findings

Mild fetal pelviectasis is one of the more common abnormalities detected by second trimester ultrasound examination, with a reported incidence of 0.5%–5% in unselected pregnant populations. Diagnostic criteria differ but generally include a second trimester renal pelvis diameter of more than 4 mm and less than 10 mm and a third trimester renal pelvis diameter of more than 7 mm and less than 10 mm. Renal pelvis diameters of 10 mm or greater are always considered abnormal. Some experts consider mild fetal

pelviectasis to be a soft marker for aneuploidy, especially trisomy 21. When mild, fetal pelviectasis is an isolated finding, the prognosis is good, and the condition often resolves either in utero or during early childhood. In a metaanalysis it was reported that only 11% of children with a history of mild fetal pelviectasis demonstrated postnatal disease. The authors of a prospective cohort follow-up study reported uropathy in 18% of their cases. Authorities thus recommend a postnatal follow-up renal ultrasound examination approximately 1 week after birth and, if necessary, at 1 month of life to document resolution (Lee et al., 2006; Coelho et al., 2007; Nguyen et al., 2010; Sohaey, 2008d; Ebrashy et al., 2016).

Car Seats and the Newborn Car Seat Challenge

All states have laws that require the use of car seats for children. It is important that parents purchase only approved car seats, so bargain-hunting at used child equipment stores should be done with caution. Lists of approved seats are available online at websites such as <https://www.healthychildren.org/English/safety-prevention/on-the-go/Pages/Car-Safety-Seats-Product-Listing.aspx>.

The observation that preterm newborns had episodes of hypoxia when monitored in car seats led the AAP to recommend in 1991 that preterm newborns be observed and monitored for apnea, bradycardia, or oxygen desaturation in their car safety seat before hospital discharge—the so-called car seat challenge (American Academy of Pediatrics Committee on Injury and Poison Prevention and Committee on Fetus and Newborn 1991, 1996; American Academy of Pediatrics Committee on Injury and Poison Prevention, 1999). In the United States, the car seat challenge expanded to include late preterm newborns, most of whom did not have respiratory problems during their hospital stay. It has been reported that 25% of late preterm newborns do not fit securely into standard car safety seats, and 12% of healthy late preterm newborns have apneic or bradycardic events in their car seats (Merchant et al., 2001). The rate of failure (about 4%) has been found to be about the same in small for GA babies as those born late preterm.

The authors of a Cochrane systematic review questioned whether or not car seat trials actually prevent morbidity or death and if there might be adverse effects from not passing this “screen,” such as prolonging the hospital stay or creating parental anxiety. Their review did not discover any randomized trials, and they concluded that “it is unclear whether undertaking a car seat challenge is beneficial or indeed whether it causes harm” (Pillely and McGuire, 2006). Since then, there has been one randomized trial in healthy term newborns comparing car seats with car beds, and no differences were found in the rates of oxygen desaturation or apnea events (Kinane et al., 2006). A study comparing a polysomnogram with the car seat challenge showed that the challenge has a low negative predictive value when compared with polysomnogram (Schutzman et al., 2013).

Routine and Common Medical Treatments

Prevention of Ophthalmia Neonatorum and Conjunctivitis

Approximately 15%–20% of babies will develop conjunctivitis in the first few weeks of life. Conjunctivitis can be caused by a sexually transmitted bacterium, normal skin or nasopharyngeal flora, or chemical irritation (Krohn et al., 1993). In addition, eye discharge

can be caused by obstruction of the nasolacrimal duct rather than from conjunctivitis. The most worrisome infection is that of *Neisseria gonorrhea*, which can invade the cornea in a matter of hours and lead to blindness. Despite effective preventive measures known since the 1880s, thousands of children are still blinded by this infection worldwide each year.

Most states in the United States have laws or regulations requiring administration of topical antibiotic ointment to the conjunctivae of babies within a few hours of birth. This practice has been effective in reducing the cases of blindness caused by gonococcal conjunctivitis. It is moderately effective in preventing conjunctivitis caused by chlamydia. The main risk of antibiotic ointment application is that it may cause a chemical conjunctivitis. Silver nitrate solution instilled into both eyes immediately after birth was the standard of care for many years, but it caused a high rate of chemical conjunctivitis.

Parents may question the need to expose their babies to eye medication, especially if the mother has been tested and found to be without gonorrhea or chlamydia. Some countries have stopped routine administration of eye prophylaxis. In those countries, an increase in infection, primarily caused by chlamydia, has been noted.

There has been an ongoing search for alternative prophylaxis that causes less chemical conjunctivitis and is not in an ointment base. A variety of prophylactic treatments have been recommended, including 1% nitrate solution, 1% tetracycline solution, 1% erythromycin solution, 2.5% povidone–iodine solution, fusidic acid, and freshly expressed breast milk. Among those, tetracycline has been reported as most effective (Zuppa et al., 2011). There is lay literature recommending the instillation of colostrum or breast milk into the eyes of babies to prevent or treat conjunctivitis. Although colostrum has antimicrobial action, its efficacy has not been adequately studied.

Povidone–iodine solution has been shown to be more effective and cause less irritation than erythromycin ointment. It is also less expensive but is not yet approved for this use by the US Food and Drug Administration (Ali et al., 2007). A major concern is that medical errors can occur if povidone–iodine soap is mistakenly substituted for the solution; it can cause eye damage. Fusidic acid has been used for preoperative prophylaxis for a number of surgical procedures in adults. However, data on its use in newborns are limited (Zuppa et al., 2011).

Vitamin K

Vitamin K is necessary for biologic activation of several human proteins, most notably coagulation factors II (prothrombin), VII, IX, and X. Since placental transfer is limited, umbilical cord blood levels of vitamin K₁ (phyloquinone) are 30-fold lower than maternal levels. Intestinal bacteria synthesize menaquinone (vitamin K₂), which has 60% of the activity of phyloquinone. However, neonates have a decreased number of bacteria in their gut that manufacture vitamin K₂; levels of this form of vitamin K are not found in the livers of infants until they are 2–3 months old. Thus newborns are deficient in vitamin K at birth and are at risk of significant bleeding. Fortunately, intramuscular (IM) vitamin K rapidly activates clotting factors, greatly decreasing this risk.

Three presentations of vitamin K–deficient bleeding (VKDB) have been described. “Early” VKDB presents in the first 24 hours after birth, is not prevented by postnatal administration of vitamin K, and usually occurs in newborns born to mothers who are taking medications that inhibit vitamin K. Common medications that

inhibit vitamin K include many anticonvulsants, isoniazid, rifampin, warfarin, and some antibiotics, such as cephalosporins. Early VKDB is frequently serious because of intracranial and/or intraabdominal hemorrhage. It is estimated that in neonates at risk of early VKDB the incidence is as high as 12% (Van Winckel et al., 2009).

“Classic” VKDB occurs in newborns during the first week of life. Although the presentation is often mild, blood loss can be significant, and intracranial hemorrhages have been reported. Although estimates differ, the incidence of classic VKDB, in the absence of vitamin K supplementation, is 0.25%–1.7% (American Academy of Pediatrics Committee on Fetus and Newborn, 2003).

“Late” VKDB occurs between the ages of 2 and 12 weeks and is usually severe. The mortality rate from late VKDB is approximately 20%, and 50% of infants with this disorder develop intracranial hemorrhages. Late VKDB is associated with exclusive breastfeeding. Human milk contains only 1–4 µg of vitamin K per liter, while commercially available formula contains 50 µg/L or more. In exclusively breastfed neonates who do not receive supplemental vitamin K, the incidence of late VKDB is estimated at 4.4–7.2 per 100,000 (or 1 per 15,000 to 1 per 20,000) (Van Winckel et al., 2009).

Vitamin K administered shortly after birth is effective in preventing classic and late VKDB. Since 1961, the recommended dose of vitamin K for term newborns born in the United States has been 1 mg given intramuscularly. However, the results of a study suggesting an association between intramuscularly administered vitamin K given at birth and childhood cancer created controversy regarding this practice (Golding et al., 1990, 1992). The results of subsequent studies strongly suggest that there is no increased risk of solid tumors in children given vitamin K intramuscularly (Puckett and Offringa, 2000).

Because of those previous concerns regarding an increased risk of childhood cancers, a switch to orally administered vitamin K occurred in some countries but not in the United States. It is apparent that a single oral dose of vitamin K has efficacy similar to that of an IM dose in preventing classic VKDB but offers less protection against late VKDB. Repeated doses of an oral vitamin K preparation until an infant is 8–12 weeks old increases the efficacy of this route of administration. However, it is not clear that even multiple doses of an oral formulation of vitamin K are as effective as a single IM dose given at birth. In a multinational review, the rates of late VKDB in infants receiving various regimens of orally administered vitamin K were mostly in the range of 1.2–1.8 per 100,000 compared with no cases in 325,000 children receiving an IM dose (Cornelissen et al., 1997). The oral regimens assessed included a birth dose of 1 mg. The reported rates of VKDB in newborns who received 2 mg orally at birth, with repeated doses subsequently, are lower but still somewhat higher than in neonates treated with intramuscularly administered vitamin K (Von Kries et al., 2003; Busfield et al., 2007). Early data from the Netherlands where infants received 1 mg orally at birth and 25 µg daily for up to 12 weeks suggested that this regimen was as efficacious as an IM dose (Cornelissen et al., 1997). However, in a subsequent study from the Netherlands, the rate of late VKDB was 3.2 per 100,000 in a group of infants with undiagnosed biliary atresia who had been treated with this dosing schedule (van Hasselt et al., 2008). Unrecognized cholestatic liver disease is a significant risk factor for VKDB. Finally, no cases of late VKDB were found among 396,000 Danish infants who received an oral dose of 2 mg of vitamin K at birth and 1 mg weekly until the age of 3 months (Hansen et al., 2003).

Highlighted by the reports of intracranial hemorrhages in four newborns from Tennessee who did not receive vitamin K at birth, there are concerns that the rate of parental refusal of vitamin K in the United States is increasing (Centers for Disease Control and Prevention, 2013; Schulte et al., 2014). Although there has been little widespread surveillance on the rates of vitamin K refusals, recent studies suggest that the rates in North America may be in the 0.3%–0.8% range; the rates are higher for newborns born at birthing centers rather than in a hospital (Sahni et al., 2014; Hamrick et al., 2016). Rather than being concerned about the reports linking vitamin K with childhood cancers, parents who refuse vitamin K treatment for the newborn are also more likely to refuse vaccines for their children at later ages and share many of the beliefs of other parents refusing vaccines for their children (Hamrick et al., 2016). In one study the most commonly cited reason for parents refusing vitamin K treatment for their newborns was “synthetic or toxic ingredients,” followed by concerns about an “excessive dose” and side effects; only 7% of those surveyed were concerned about the risks of cancer (Hamrick et al., 2016).

The risks from intramuscularly administered vitamin K include pain at the injection site and the possibility of a serious medication error. The risks of a significant complication from the injection are probably negligible; in one study, zero significant complications were reported after 420,000 injections (Von Kries, 1992). In the United States, oral administration is complicated by the lack of an oral vitamin K preparation licensed for newborns. In some settings, infants have received the IM preparation orally. However, tolerability may be a problem, and the efficacy of this preparation when given orally may not be comparable with the oral formulations used in Europe. In addition, adherence with repeated doses of orally administered vitamin K in infants may be suboptimal. Finally, it is unknown whether the use of repeated administration of an oral vitamin K preparation in the dose range of 1–2 mg each week is associated with an increased risk of childhood cancers.

For parents who have questions regarding the best method to prevent classic and late VKDB, the clinician is advised to discuss the pros and cons of IM versus oral administration of vitamin K. If the parents choose oral administration, a dose of 2 mg of vitamin K should be given shortly after birth, with subsequent doses until the newborn is at least 4 weeks old if he or she is breastfed. In a policy statement, the AAP suggests that if an oral vitamin K formulation becomes licensed for use in the United States, a 2-mg dose may be given at birth and repeated at 1–2 weeks of age and at 4 weeks of age for neonates whose parents decline IM vitamin K treatment (American Academy of Pediatrics Vitamin K Ad Hoc Task Force, 1993).

Circumcision

Neonatal circumcision is a polarizing issue for both healthcare professionals and parents. Those who favor routine circumcision highlight health benefits such as decreased risk of urinary tract infections (UTIs), reduced risk of penile cancer, and possibly lower rates of sexually transmitted infections, including HIV (Schoen, 2008). Those who oppose the procedure point out that the number of circumcisions needed to be performed to prevent one of these outcomes (number needed to treat) is large, that the risks of the procedure balance out the benefits, that circumcision leads to loss of sexual sensation, and that subjecting a neonate to a painful procedure without clear benefits may be unethical (Andres, 2008). In 2012 the AAP published a policy statement concluding that the benefits of circumcision outweigh the risks of the procedure.

However, these health benefits were not great enough to recommend routine circumcision in all male neonates (American Academy of Pediatrics Task Force on Circumcision, 2012a).

It is clear that circumcision reduces the risk of UTI by threefold to 10-fold (American Academy of Pediatrics Task Force on Circumcision, 2012b). However, given the low incidence of UTI in male newborns, 100 boys need to be circumcised to prevent one UTI. Similarly, although circumcision has been shown to prevent penile cancer, this is an extremely rare condition, and the number needed to treat is about 900 (Christakis et al., 2000). The results of studies in three African countries indicate that circumcision reduces the risk of HIV infection by 56% (Mills et al., 2008). In the United States, where HIV infection rates are lower, it has been estimated that circumcision might decrease the acquisition of HIV through heterosexual transmission by 16%; 298 boys would need to be circumcised to prevent one case of HIV infection (Sansom et al., 2010). There is limited evidence suggesting that circumcision might reduce the risk of other, selected, sexually transmitted infections, including syphilis and genital herpes. However, there is no compelling evidence that circumcision reduces the risk of chlamydia or gonorrhea (American Academy of Pediatrics Task Force on Circumcision, 2012b).

Circumcision is generally a safe procedure. Although some increased bleeding is reported after 1% of circumcisions, the rate of significant complications is about 0.2% (Gee and Ansell, 1976; Wiswell and Geschke, 1989; Christakis et al., 2000). Bleeding, sometimes requiring suturing of a vessel, is the most common significant complication, followed by penile injury and infection. Infection is more common following a circumcision using a Plastibell rather than a Gomco clamp; the incidence of hemorrhage is reportedly similar after either technique (Gee and Ansell, 1976).

Circumcision is an uncomfortable experience for the neonate. Small amounts of sucrose solutions can be offered to the baby for soothing. Pain from the actual surgery can be significantly decreased with the use of a dorsal penile nerve block or ring block (American Academy of Pediatrics Task Force on Circumcision, 2012b). In one study, 65% of newborns who had received a dorsal nerve block had no or minimal response to the initial clamping of the foreskin (Taeusch et al., 2002). However, the results of a randomized controlled trial suggest that ring block provides superior analgesia compared with dorsal penile nerve block (Lander et al., 1997). Although topical anesthesia may be better than no anesthesia, it provides inferior pain relief compared with dorsal penile nerve block (Brady-Fryer et al., 2004).

A poor cosmetic outcome can be caused by removal of too little foreskin. It has been estimated that 1%–9.5% of circumcisions are redone because of parental concern regarding the appearance. In a prospective study among boys younger than 3 years who had been circumcised with use of either a Plastibell clamp or a Mogen clamp, the glans was fully exposed in only 35.6%. However, in older circumcised boys, the glans was fully exposed in more than 90% (Van Howe, 1997). This suggests that parents of a circumcised infant should be counseled that the vast majority of properly done circumcisions will lead to an acceptable cosmetic appearance over time.

In the United States the Gomco clamp is the most commonly used apparatus for performing circumcisions, followed by the Plastibell clamp and the Mogen clamp (Stang and Snellman, 1998). The use of the Mogen clamp, which was designed by a Jewish mohel, leads to shorter procedures and, reportedly, less pain and bleeding than the other techniques (Reynolds, 1996; Kurtis et al., 1999; Taeusch et al., 2002). However, less foreskin is removed

with the use of the Mogen clamp than with the other two techniques (Alanis and Lucidi, 2004).

Hepatitis B Vaccine

The implementation of routine HBV immunization during infancy has been associated with a dramatic decrease in the incidence of this infection. Between 1990 (before routine vaccination of infants) and 2004 the overall incidence of acute HBV in the United States declined by 75% and by 94% among children and adolescents (Centers for Disease Control and Prevention, 2005). Both the Centers for Disease Control and Prevention and the AAP recommend that the initial dose of the three-dose HBV immunization series be given in the newborn nursery. However, this recommendation is not universally followed; the rate of receipt of a birth dose of HBV vaccine in United States was estimated at 72.4% in 2014. The rates differ substantially across the United States, ranging from 88.4% among newborns born in North Dakota to 48.4% among those born in Vermont (Hill et al., 2015).

There are at least two advantages of providing the first dose of HBV vaccine during the newborn nursery stay. First, newborns who receive a birth dose are more likely to complete their HBV immunization series on time than those who receive a first dose later (Yusuf et al., 2000). Secondly, since a dose of HBV vaccine given within 12 hours of birth can prevent vertical transmission of HBV infections in 75%–90% of cases, early provision of immunization serves as a “safety net” in cases where there has been an error in identifying a mother who is HBV surface antigen positive (Centers for Disease Control and Prevention, 2005).

The main disadvantage of providing a dose of HBV vaccine during the nursery stay is that it may complicate documentation of HBV immunization status in a child by increasing the number of vaccination providers. There is no evidence that administration of a birth dose of HBV vaccine leads to more evaluations for sepsis because of adverse events related to the immunization.

Ongoing Care

Umbilical Cords

Umbilical Cord Variants

At the time of delivery a description of the umbilical cord should be documented in the medical record as there may be long-term implications for care of the newborn if there are cord abnormalities. A great deal has been written about cords with a single umbilical artery, but other variations are also important.

Short cords are associated with decreased fetal movement and may indicate an underlying neuromuscular disorder or genetic syndrome. This decreased fetal movement may also cause a decrease in bone density in the newborn (Krakowiak et al., 2004; Wright and Chan, 2009).

Long cords are associated with large and active babies and more often are found in males. They are associated with an increased risk of cord compression, entrapment, knotting, and nuchal cords (Sornes, 2000). True knots may cause problems for the fetus during pregnancy and may also compress at the time of delivery, causing additional compromise. In the presence of chronic cord compression, neonates have an increased risk of brain imaging abnormalities (Baergen et al., 2001). Velamentous insertions of the umbilical cord are associated with an increase in obstetric complications such as vasa previa and cord rupture (Hasegawa et al., 2006).

A single umbilical artery is detected in about 4 in 1000 births and is associated with a number of congenital anomalies, including renal or genitourinary malformations, cardiac malformations, and chromosomal anomalies, including Down syndrome, but most newborns with a single umbilical artery are normal. In this era of near universal prenatal fetal ultrasonography, many of the associated anatomic abnormalities are discovered before delivery (Johnson and Tennenbaum, 2003; Deshpande et al., 2009). Unless there are additional problems noted on physical examination of the newborn, there is no need to repeat diagnostic ultrasound examinations after the birth of a newborn with a single umbilical artery.

Prevention of Omphalitis

The recommendations for umbilical cord care may range from “dry cord care” to use of dyes and/or cleansing with alcohol, soap and water, or antiseptics. Concerns over the possible toxic effects of dye and antiseptics led many hospitals in the United States to adopt the “dry cord care” method of cord care. Unfortunately, this may be causing an increase in the risk of omphalitis (Janssen et al., 2003; Simon and Simon, 2004). In one review a 50% reduction in omphalitis and a 12% reduction in neonatal mortality was found when chlorhexidine was used versus standard dry cord care methods (Sinha et al., 2015). This was the same conclusion reached in a review of home births in developing countries, but no clear difference was found in developed countries (Imdad et al., 2013). If the dry cord method is used, parents and healthcare providers should watch for redness around the umbilical cord stump.

Tetanus neonatorum, with the infection occurring via the umbilical cord, continues to be reported in more than 20 developing countries, resulting in 58,000 neonatal deaths per year. The condition is related to low vaccination rates in women of childbearing age, home deliveries, and certain cultural care practices. Public health efforts focusing on effective vaccination programs and use of “clean bed” deliveries are needed to eliminate the disease (Thwaites et al., 2015).

Delayed Cord Clamping

The results of several studies suggest a benefit to delaying clamping of the umbilical cord at birth. This practice has been shown to benefit term as well as preterm newborns. The babies are more hemodynamically stable, have greater red cell mass and iron stores during infancy, and have improved neurodevelopmental outcome during childhood. These findings have led to the endorsement of policies to delay cord clamping by both the AAP and the American College of Obstetrics and Gynecology (McAdams, 2014). With delayed cord clamping, there is an increase in the risk of mild polycythemia and an increase in risk of jaundice but not increased treatment for these conditions.

While current guidelines call for a 30–60-second delay before clamping, it seems beneficial to wait for the baby to show physiologic readiness. Babies who cry vigorously may be ready for clamping sooner than quiet babies. An ultrasound study of blood flow through the umbilicus showed arterial and venous flow may not stop for 3 minutes (Boere et al., 2015).

Umbilical Cord Blood Banking

The practice of banking umbilical cord blood is increasing worldwide. This service is offered by both public and privately supported entities; however, the quality of service is better regulated in public blood banks. While there are controversies, the potential for use of stem cells is growing, and there will likely be an increased demand for this service (Yoder, 2014). One of the greatest barriers

to more consistent collection of umbilical cord blood is that current hospital practices generally do not support this service (Broder et al., 2013).

Breastfeeding

Benefits of Breastfeeding

There is voluminous evidence that the optimal nutrition for normal neonates is human milk provided via the mother's breast. Growing evidence supports the role of human milk in prevention of early onset of allergies, prevention of adult obesity, reduction in severity and frequency of infections (including those leading to hospitalization in developed countries and those leading to death in developing countries), and increased intellectual functioning (Section on Breastfeeding, 2012). It is a public health imperative and incumbent on our society to provide systems that support breastfeeding (Christakis, 2013).

Support of Breastfeeding

Breastfeeding is not always the “easy and natural” undertaking it is touted to be. Primiparous mothers report more difficulties than multiparous mothers. Breastfeeding support begins with encouragement and education at prenatal visits. After birth, in-person lactation support is helpful in promoting both initiation and persistence of nursing (Renfrew et al., 2012). Places of employment should provide support by having adequate maternity care leave policies, improving facilities, and having policies allowing time and space for nursing and pumping for lactating women at the workplace (Sattari et al., 2013). Fathers and grandparents should provide a supportive social network by performing homecare tasks to facilitate rest for lactating mothers (Alvarez et al., 2015). Problems with nursing should trigger additional intervention with lactation specialist evaluation and advice.

In 1991 the World Health Organization and the United Nations Children's Fund developed a program to promote breastfeeding called the Baby-Friendly Hospital Initiative (BFHI). As a comprehensive program, implementation of the 10 steps of the BFHI (Box 26.2) has been shown to significantly increase the rates of breastfeeding (Kramer et al., 2001). In addition, there is evidence of a “dose–response” relationship between the number of BFHI steps that women are exposed to and improved breastfeeding outcomes (Perez-Escamilla et al., 2016).

• BOX 26.2 Baby-Friendly Hospital Initiative: Ten Steps to Successful Breastfeeding

1. Maintain a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their newborns.
6. Give newborns no food or drink other than breast milk unless medically indicated.
7. Practice “rooming-in”—allow mothers and newborns to remain together 24 h a day.
8. Encourage unrestricted breastfeeding (breastfeeding on demand).
9. Give no pacifiers or artificial nipples to breastfeeding newborns.
10. Foster the establishment of breastfeeding support groups, and refer mothers to them on their discharge from the hospital or clinic.

For some of the individual steps of the BFHI, such as excluding the use of pacifiers, the evidence is contradictory (Cramton et al., 2009; O'Connor et al., 2009). There are a number of epidemiologic studies showing cessation of breastfeeding is associated with pacifier use, but the few randomized prospective trials done give different results. The authors of a review concluded that among mothers who were motivated to breastfeed, pacifier use did not significantly affect the prevalence or duration of breastfeeding (Jaafar et al., 2012). Sucking is a primitive brain self-soothing process. Babies with certain temperaments may benefit more than others by using sucking to self-soothe. Pacifier use has been shown in some studies since the 1970s to decrease the risk of sudden infant death syndrome (SIDS), and in premature infants, nonnutritive sucking actually enhances weight gain. The AAP developed a policy statement supporting pacifier use but recommended waiting until approximately 1 month of age (Section on Breastfeeding, 2012). The important issue is whether or not the use of a pacifier is replacing feedings, so if a mother is motivated to breastfeed and maintains a frequency of 8–12 feedings per day, the use of a pacifier between meals seems reasonable.

Another contentious issue is the use of supplemental formula during the initial newborn period. The results of a randomized prospective trial indicated that use of limited supplemental formula was associated with increased breastfeeding rates at 3 months of age (Flaherman et al., 2013). That seems contradictory to earlier studies showing a decline in nursing when formula samples or discharge packages were given to families. One key difference is that in the trial, formula use was limited to 10 mL after feedings, administered via a syringe, and supplement was discontinued once mature milk was produced. More research is needed to determine which mother–infant dyads will benefit from supplement while avoiding sabotage of breastfeeding.

From a practical standpoint there are several evidence-based interventions during the newborn nursery stay that increase the rate and/or duration of breastfeeding. These include the use of frequent demand feedings as opposed to a rigid feeding schedule, early skin-to-skin contact between the mother and the newborn, professional advice on breastfeeding techniques, and exclusion of commercial formula from discharge packs (Donnelly et al., 2000; Renfrew et al., 2000; Anderson et al., 2003; Britton et al., 2007).

In an era of early hospital discharge for healthy newborns, it is particularly important to have in-home or clinic follow-up at age 3–4 days. This is when the newborn's weight reaches its nadir, jaundice peaks, lactogenesis II is starting (see later), and mothers are sleep deprived because of dealing with the around-the-clock needs of the newborn. Breastfeeding mothers may need extra encouragement during this time and continued vigilance to ensure that breastfeeding is established.

Breastfeeding Problems

Breast milk development is divided into two or three phases: lactogenesis I occurs during pregnancy with breast enlargement due to proliferation of ducts and lobules and later in pregnancy with colostrum production. Lactogenesis II occurs usually about 56–72 hours after birth; gonadotropin and progesterone levels decline and prolactin level increases (Dewey et al., 2003). This phase is characterized by the rapid increase in milk volume—sometimes this is exuberant to the point of engorgement. Lactogenesis III occurs generally after 1 month of nursing when the milk composition and volume are responsive to the reciprocal relationship between the mother and her baby—a demand and

• **Fig. 26.2** Prevalence of reported breastfeeding concerns by mothers by newborn age. (Modified from Wagner EA, Chantry CJ, Dewey KG, Nommsen-Rivers LA. Breastfeeding concerns at 3 and 7 days postpartum and feeding status at 2 months. *Pediatrics*. 2013;132:e865–e875.)

supply feedback loop. Some experts combine lactogenesis II and lactogenesis III into one phase.

Delays in lactogenesis II have been shown to occur after cesarean birth, in poorly controlled diabetic mothers, when there is stress during delivery, when there are retained placental fragments, and when there is pituitary failure. There are some situations when no milk production occurs, leading to frustration and feelings of failure in mothers. The timing of lactogenesis II is a biologic clock that cannot be accelerated by pumping or frequent nursing (Chapman et al., 2001; Flaherman et al., 2012a).

More than 90% of mothers report concern and difficulty with nursing during the first 10 days after delivery (Fig. 26.2) (Wagner et al., 2013). Combined with hormonal changes and sleep deprivation, this can compound the risk of postpartum depression and early cessation of nursing. Postpartum depression should be screened for at health supervision visits until the infant is 6–12 months of age (McLearn et al., 2006).

Common issues that may lead to early cessation of nursing include nipple pain, newborn jaundice, excessive weight loss or poor weight gain, concern about maternal medications, and lack of social support. There are also conditions associated with low milk volume production, including maternal factors (lack of social support, prenatal confidence and expectations about breastfeeding, timing of return to work, inadequate frequency of nursing, inadequate breast tissue, flat or inverted nipples, or very large breasts) and baby factors (hypotonia, drug withdrawal, asymmetric jaw, high arch palate, poor tongue motor abilities, and temperamental issues).

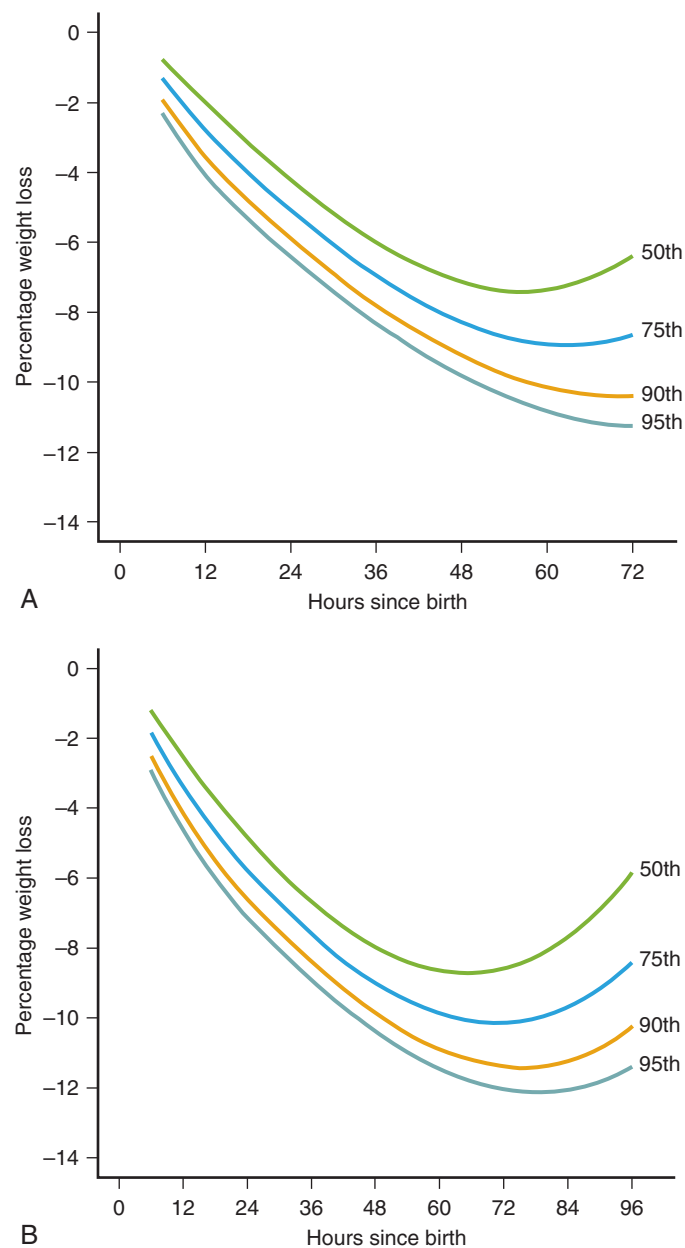

For nipple pain there is no treatment that is clearly advantageous (e.g., hydrogel, lanolin, breast milk, shields), but education on latch position is helpful. For most, the pain decreases within the first 7 days regardless of the treatment selected (Dennis et al., 2012). In a review of nipple shields, McKechnie and Eglash (2010)

found a lack of randomized trials but expressed concern about shields interfering with milk transfer.

There has been a recent increase in the use of frenotomy to alleviate pain with nursing, presumably due to a tight lingual frenulum (tongue-tie or ankyloglossia). With use of objective rating scales, the rate of tongue-tie in newborns is about 1%–4%, but more infants are undergoing frenotomy, and there are concerns that this may be more due to anecdotal reports rather than more rigorous study (Power and Murphy, 2015). Sometimes frenotomy is done to alleviate the frustrations of mothers (and lactation specialists) who are dealing with breastfeeding problems of unknown origin. There are only a few prospective studies on frenotomy, and the results are contradictory (Power and Murphy, 2015). It may be prudent to wait until the physiologic process of lactogenesis II and early nipple pain have passed before frenotomy is considered. Although the procedure is simple and relatively free of side effects, unnecessary interventions or labeling of a newborn as abnormal should be avoided in newborn care whenever possible. Frenotomy for posterior tongue-tie has received extra scrutiny because evidence is lacking that supports the diagnosis and outcome from treatment, and the procedure is more invasive (Douglas, 2013).

Jaundice has become more prevalent with the resurgence of breastfeeding. Along with more visible jaundice, there has been an increase in concern and anxiety about the risks associated with jaundice. Most jaundice is physiologic and resolves with onset of lactogenesis II. It is important for providers who care for newborns not to overestimate the risks, while maintaining vigilance for the exceptionally rare case when there is true risk. The bilirubin level should serve as a call for action to emphasize lactation support rather than lead to a separation of the newborn from the mother and artificial feeding to lower the bilirubin level.

The normal newborn is born with a surplus of extracellular free water, and in cesarean delivery births, mothers are often given

• **Fig. 26.3** Nomograms of weight loss in exclusively breastfed newborns born vaginally (A) or by cesarean delivery (B). (Modified from Flaherman VJ, Schaefer EW, Kuzniewicz MW, et al. Early weight loss nomograms for exclusively breastfed newborns. *Pediatrics*. 2015;135:e16–e23.)

additional boluses of fluids that may further hydrate the newborn (Chantry et al., 2011). It is normal, expected, and perhaps preferable that babies will lose this free water in the first 72 hours of life. This free water is protective of the newborn's fluid balance while the mother's milk is awaited (Mulder and Gardner, 2015). In cases of extra hydration, extra weight loss may be expected. The average term newborn loses about 7% of birthweight, with 12% of newborns born vaginally losing more than 10% of birthweight (Fig. 26.3) (Flaherman et al., 2015). The loss during the first 24 hours of life can predict those who will lose more. This is not a state of dehydration but is a normal physiologic adaption to extrauterine life, so healthcare providers should not alarm parents or suggest that there is something wrong with their baby.

With the onset of copious production of mature milk, neonates begin to gain weight and their serum sodium levels fall (Marchini and Stock, 1997). Newborns fed human milk regain their birthweight, on average, by the age of 8.3 days; 97.5% have regained their birthweight by 21 days (Macdonald et al., 2003). In newborns who lose substantially more than 10% of their birthweight because of breastfeeding difficulties, there is the potential for significant hypernatremia (Oddie et al., 2013).

Supplementation of Breastfeeding

It is usually unnecessary to provide any nutrition or fluid to term breastfed newborns beyond human milk. Dextrose water or commercial formula may be needed in neonates with hypoglycemia who are not responsive to breastfeeding. Supplementation may also be indicated in newborns who have lost more than 10% of their birthweight and/or have decreased urine and stool output or in the presence of significant hyperbilirubinemia. Supplementation should be considered a temporary intervention, and its provision should not interfere with the onset of successful breastfeeding.

Temporary supplemental formula or expressed breast milk when available can be provided via a supplemental nursing system, finger feeding, or a bottle. Of greatest importance is close monitoring of the change in weight of the baby and continued lactation support. The use of banked or donor milk is increasing, but there has also been increased concern about the use of the unregulated milk that may be available. Some milk has been diluted with formula and may contain infectious diseases. Publicly supported milk banks that follow the recommendations of the World Health Organization use pasteurization and quality control to provide safer milk (Kair et al., 2014; Steele et al., 2015).

Contraindications to Breastfeeding

The few, absolute contraindications to breastfeeding include maternal HIV infection, untreated tuberculosis in the mother, evidence of current cocaine use,¹⁵⁸ use of antimetabolite drugs, and galactosemia in the neonate (Gartner et al., 2005; Field, 2008). There are a myriad of drugs for which concern exists regarding long-term neurodevelopmental outcomes in the infant. Selective serotonin reuptake inhibitors are commonly used to treat depression and anxiety in young women. Among drugs in this category, sertraline and paroxetine are thought to be the safest for use in breastfeeding mothers, while fluoxetine and citalopram are felt to have the most potential for toxicity in the neonate (Field, 2008). Overall, few adverse effects have been noted with use of any of these drugs, and generally the potential risks associated with these medications are thought to be outweighed by the benefits of breastfeeding (Field, 2008). Similarly, although methadone is detectable in the breast milk of women receiving this medication, serum levels in neonates are quite low and unlikely to have a significant effect (Jansson et al., 2008). Online references are available that have the current status of the effects of toxins and medications in breast milk: <http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>.

Hepatitis C virus RNA has been found in the milk of mothers infected with this virus. Despite this, transmission of infection via breastfeeding has not been documented. Maternal hepatitis C is not considered a contraindication to breastfeeding (Gartner et al., 2005).

Bottle feeding

Commercial formula that provides adequate nutrition, vitamins, and minerals is available for infants of mothers who do not wish

to breastfeed their infants or in those rare instances when breastfeeding is contraindicated or impossible. There are three major categories of formula used in neonates: cow's milk-based, soy, and hydrolyzed formula. Of these, cow's milk-based formula is the most commonly used. The main carbohydrate in cow's milk-based formula is lactose. Soy formulas were developed for infants with suspected cow's milk allergy. Because the main carbohydrate in soy formulas is sucrose or corn syrup, soy formula can be used in neonates with suspected galactosemia. Protein hydrolyzate formulas were initially developed for use in infants who are highly intolerant to cow's milk protein (Kleinman, 2009b). They are purported to lead to fewer allergies in babies and children than cow's milk-based formula, but the evidence for this is limited (Osborn and Sinn, 2006). All extensively hydrolyzed formulas are lactose free (Kleinman, 2009b). Extensively hydrolyzed formulas are indicated in infants with definitive evidence of cow's milk protein allergy because 10%–14% of such children also have soy allergy (Bhatia and Greer, 2008).

Traditionally, standard preparations of formulas available for use in healthy term neonates provide 0.67 kcal/mL. This caloric density was based on the calories in human milk. However, the results of some studies indicate that the average caloric density of human milk may be closer to 0.64–0.65 kcal/mL. Because of this, some infant formulas have been modified to provide 0.643 kcal/mL (19 kcal/oz) (Marriage et al., 2015). Most formulas are fortified with iron at a concentration of 10–12 mg/L. Vitamin D at a concentration of approximately 400 IU/L is provided in all of the commercially available formulas (Kleinman, 2009a).

Mothers who elect to bottlefeed their babies report feeling unsupported in their decision by healthcare professionals, and up to 50% feel pressured to breastfeed (Lakshman et al., 2009). Although the benefits of breastfeeding should be provided to mothers who have not decided how to feed their babies, the role of healthcare providers is also to support the decision of those who have elected to bottlefeed their babies. It is also important to provide practical education about bottlefeeding to these parents; this is frequently not done in many newborn nurseries (Lakshman et al., 2009).

Newborns who are bottlefed can feed *ad lib* beginning shortly after birth. The average formula intake in term newborns during the first day of life is 15–20 mL/kg and is 40–45 mL/kg during the second day (Dollberg et al., 2001). Term newborns who are formula fed during their birth hospitalization typically lose less weight than breastfed infants (Flaherman et al., 2015; Miller et al., 2015). The median weight loss in formula-fed term newborns at 48 hours of life has been reported to be 2.9% of birthweight for those born vaginally and 3.7% among those born by cesarean delivery; weight loss of 7% or more during a typical newborn nursery stay in formula-fed infants is uncommon (Miller et al., 2015).

Anticipatory Guidance

A primary duty of newborn care providers is to ensure that the newborn's caregivers (usually the parent or parents) have the knowledge and skills to provide for their baby's normal growth and development. Parents who are well informed about normal newborn development and behavior have more realistic expectations about the work involved and look on their child with more fondness. Conversely, it is important to assess the parents' ability to provide a safe and nurturing environment for the neonate before discharge from the newborn nursery. Parents showing concerning behaviors, possibly leading to abuse or neglect, should have supervision and interventions to help them, or their parental rights should be terminated (Wattenberg et al., 2001; Davidson-Arad et al., 2003).

There are several major challenges faced by parents of normal newborns: sleep deprivation, learning how to calm a crying newborn, dealing with significant life changes, and the new worries that come with being responsible for a totally dependent being. Postpartum depression is more common and of longer duration than previously thought and is present in at least 10% of mothers. Depression also occurs in about 10% of fathers during early infancy and is related to maternal depression. This condition is related to sleep deprivation and has a major and long-lasting impact on infant homeostasis and development (Chaudron, 2003). Depression screening of parents should occur at all well-child visits during the first 6–12 months of life.

Anticipatory guidance should be given to help prepare new parents for the common tasks of newborn care and to educate them about the many normal variations in newborn behavior. Learning how to soothe a baby is one of the earliest needed parenting tasks; providers can help give suggestions both to reduce crying and to better cope with those newborns who are more sensitive and harder to soothe (Barr et al., 2009).

Most parents have questions about feeding, elimination, bathing, cord care, genital care, jaundice, and common rashes. There are numerous checklists of educational topics that can be overwhelming to new parents and providers. In addition, learning styles differ, with some preferring written materials and others preferring audiovisual materials or hands-on demonstration. Ideally, education should be targeted toward the topics of interest and with the appropriate materials for the learning style (Dusing et al., 2008).

Mothers are often not in a good learning state in the immediate postpartum period because of pain, postpartum hormonal changes, and the stress of being in a hospital. However, this is also a period of heightened receptivity to change, so attempts to teach or make lifestyle changes (e.g., smoking cessation) may be more effective. There is some evidence that providing parental education using tools such as interactive videos and computers may be superior to traditional teaching (Trepka et al., 2008; Snowdon et al., 2009). Also, DVDs provided in the nursery or along with well-child visits have been shown to be helpful. A randomized controlled trial of a 15-minute anticipatory guidance DVD linked to a well-child visit led to more parents in the DVD group feeling prepared to care for their baby after the visit, having high confidence in bathing their baby, and having high confidence in recognizing congestion when compared with the control group. Those in the DVD group also had fewer additional office visits between birth and 2 months (Paradis et al., 2011). Another effective teaching method is to perform home visits for education of parents. A metaanalysis comparing 60 home visit programs revealed improvement in parenting behaviors, faster parental return to work or school, and lower rates of child abuse (Sweet and Appelbaum, 2004).

Given the obstacles to providing meaningful education during the nursery stay, it is probably better for practitioners to focus on a few key points of anticipatory guidance rather than reciting a long litany of instructions. There is also a philosophical choice in deciding whether to emphasize the overall health of a newborn or to concentrate on prevention or identification of illness. There is little evidence about the efficacy of most anticipatory guidance provided to parents during the newborn nursery stay. A notable exception is the successful Back to Sleep campaign to reduce the risk of SIDS, discussed in the next section.

There is also emerging evidence that education regarding the normality of inconsolable crying in newborns helps parents deal with this stressful situation and may reduce the risk of shaken baby syndrome (Barr et al., 2009). A DVD entitled "Period of

Purple Crying” is provided at some newborn nurseries to parents to help prevent shaken baby syndrome by teaching calming and coping techniques. Early evaluations of the DVD indicate that it may lead to better parental knowledge about newborn crying; however, in one population-based study, provision of the DVD in newborn nurseries was not associated with a decrease in the incidence of abusive head trauma in infants (Zolotor et al., 2015).

Sleep Position

With the exception of immunizations, no child health intervention in the past 3 decades has resulted in a larger decrease in post-neonatal infant mortality than the Back to Sleep campaign. The remarkable change in the predominant sleep position of infants from prone to supine has led to a 30%–50% reduction in the rate of SIDS in the United States (American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome, 2005). A multipronged effort including brochures, public service announcements, and education provided by healthcare professionals was used to affect the change in sleep position (Willinger et al., 2000). Obviously, education provided to parents during the newborn nursery stay is a crucial determinant of the sleep position of an infant. In addition to providing education, there is evidence that parents model sleep position for their babies after how they saw nurses and physicians place their neonate in his/her bassinet in the newborn nursery (Colson and Joslin, 2002; American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome, 2005). There is no evidence that placing newborns on their side during the first few hours after birth decreases the risk of aspiration (American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome and Moon, 2011). Therefore it is crucial that neonates are placed on their backs to sleep in the newborn nursery. In addition, there is an additive effect from both physicians and nurses recommending and demonstrating the supine sleep position (Willinger et al., 2000).

In addition to the supine position, there are other factors related to the sleep environment that may impact the risk of SIDS. It is recommended that infants sleep on firm surfaces and without excessive bedding such as pillows. Although a controversial topic, the results of a metaanalysis strongly indicate that cosleeping increases the risk of SIDS by nearly threefold. The risk of cosleeping is highest in infants of mothers who smoke (Vennemann et al., 2012). In addition, although use of a pacifier has been found to reduce the risk of SIDS, there is a reluctance to recommend these devices because of concerns about reducing breastfeeding (American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome, 2005; American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome and Moon, 2011).

Discharge and Follow-Up

The average length of the initial hospital stay for US newborns born at 35 weeks’ gestation or later is 48–52 hours (Datar and Sood, 2006; Paul et al., 2006; Kuzniewicz et al., 2009). Since approximately 50% of newborns delivered vaginally are discharged before 48 hours after birth and up to 40% of those born by cesarean delivery are discharged before 72 hours after birth, a large proportion of newborns are discharged before 3–4 days after birth, which is when bilirubin levels typically peak and breastfeeding is well established (Paul et al., 2006). It is recommended that newborns discharged before 48 hours after birth have a follow-up appointment with a provider within 48 hours (American Academy of Pediatrics

Committee on Fetus and Newborn, 2004). This follow-up can be accomplished either by a visit to a healthcare provider or by a home nursing visit.

The risk factors for readmission following an initial hospital stay of less than 48–72 hours include GA of less than 39 weeks (and especially <37 weeks), primiparous mother, and Asian race (presumably because of an increased risk of hyperbilirubinemia) (Liu et al., 1997; Grupp-Phelan et al., 1999; Paul et al., 2006; Burgos et al., 2008). Consideration of a longer nursery stay is suggested for newborns with one or more of these risk factors. In addition, early discharge is not recommended for term newborns who have not voided, passed at least one stool, or demonstrated adequate breastfeeding (American Academy of Pediatrics Committee on Fetus and Newborn, 2004). However, there is little evidence to support these recommendations.

Common Problems During the Nursery Stay

Hypothermia and Hyperthermia

Being too cold or too hot causes metabolic stress to the newborn, so efforts to maintain a steady and neutral thermal environment should be made. The best practice is to dry the baby immediately after delivery and place the newborn skin-to-skin with the mother. Although the AAP and the American College of Obstetricians and Gynecologists jointly recommend keeping newborns’ core temperatures within the narrow range of 36.5°C to 37°C, in one study of healthy term newborns the average temperature was 36.5°C, with a normal range from 36.0°C to 37.9°C (Takayama et al., 2000). Thin babies tend to have lower body temperatures, and heavier babies tend to have higher body temperatures. Bathing a newborn often causes hypothermia. This is less likely when bathing is performed from trunk to head or when a bath is used versus washing with a cloth.

Standard practice at most nurseries is to measure axillary temperatures, probably because of reports in the 1960s and 1970s of rare perforations caused by rectal thermometers; however, axillary temperatures may not always accurately reflect core temperature (Hutton et al., 2009). Importantly, axillary temperatures are not the standard used in studies of sepsis in infants younger than 2–3 months of age.

Hypothermia

On leaving the womb a newborn is immediately challenged with maintaining a normal body temperature. If a neonate is not quickly dried at birth, he or she may lose up to 1°C body temperature per minute. Healthy term babies are able to increase heat production through glycogenolysis and nonshivering thermogenesis for minutes to a few hours, depending on environmental conditions (Aylott, 2006). Babies typically experience a decline in body temperature during the first hour after birth, with a gradual increase during the following 12 hours (Li et al., 2004). By the second day the newborn’s body temperature becomes more stable, but heat loss can occur again with bathing or other stresses (Takayama et al., 2000).

Many nurseries worldwide have adopted policies to delay bathing to avoid hypothermia, to allow time for initial bonding, and to promote breastfeeding. Early skin-to-skin contact between the newborn and the mother is useful both to prevent and to treat early temperature loss, but attention to positioning and frequent checks by nursing staff are required (George et al., 2015). Hypothermia should be managed by the baby being placed skin-to-skin with a parent or under a radiant warmer.

Hyperthermia

An elevated body temperature at birth generally reflects the intrauterine temperature and is not usually a sign of sepsis (Baumgart, 2008). Isolated hyperthermia during labor is associated with neonatal encephalopathy, occurring in approximately 1 in 2000 births (Blume et al., 2008). After the first 3–4 days of life, increased temperatures are most likely caused by dehydration from suboptimal breast milk supply (Maayan-Metzger et al., 2003). A single increased temperature in an otherwise normally behaving newborn is not a strong predictor of infection but has been reported as a sign of intracranial hemorrhage (Fang et al., 2008).

Elimination

Urination

Approximately 15% of healthy newborns void at the time of delivery, and 95% void by 24 hours of age. Delayed voiding is likely a consequence of stress on the newborn during labor and delivery, which is a protective mechanism for the baby (Vuohelainen et al., 2007, 2008). Normally, no intervention is needed once homeostatic adaptation to extrauterine life has been established.

The differential diagnosis of delayed voiding (defined as no urine output by 24–48 hours of age) includes renal and postrenal causes. With the frequent use of prenatal ultrasound examination, it is unusual for a significant renal anomaly to be unknown before birth. Most newborns with bilateral renal agenesis have other findings, such as oligohydramnios or Potter sequence. Unilateral renal agenesis does not usually give signs of decreased urine output. Renal vascular thrombosis can cause anuria, and babies with this condition are usually ill. Severe cystic kidney disease can involve urinary outflow obstruction. The diagnosis of cystic kidneys is usually made after the newborn period or is found incidental to evaluation of other anomalies and not because of delayed voiding.

Postrenal causes of delayed voiding include neuropathic bladder dysfunction and anatomic obstruction of urinary flow by anomalies in ureters, the bladder, or the urethra. Persistent or recurrent bladder distention after catheterization is found with occult lower spinal cord anomalies. Presacral teratoma or other tumors can cause compression and urinary blockage as well. In male newborns, there is the possibility of posterior urethral valves. Congenital lower urinary tract obstruction occurs in 1 in 3000 births, with two-thirds of these due to posterior urethral valves. Physical findings of loose abdominal skin or musculature and a distended bladder suggest this diagnosis (Malin et al., 2012).

In a healthy-appearing newborn who has a normal physical examination and a history of a normal prenatal ultrasound, allowing up to 72 hours for a spontaneous first void will avoid excessive testing. In fussy neonates and neonates with other genitourinary abnormalities, enlarged kidneys, or a distended bladder, testing should begin immediately. Ultrasound examination of the bladder, kidneys, and posterior urethra is often diagnostic.

Normal newborns have decreased renal concentrating ability and excessive extracellular free water at birth. As a result, they will continue to void despite low intake of fluids. This process is normal. Newborns maintain normal hydration despite weight loss. Conversely, delayed voiding is not indicative of dehydration in the first 72 hours after birth. When mothers undergo cesarean section, the fluid boluses given to prevent hypotension may result in additional free water in their newborn. This can lead to greater than 7% birthweight loss with extra voiding (i.e., a physiologic diuresis)

(Mulder et al., 2010). Hearing about weight loss in their newborn creates stress, guilt, and anxiety in parents, which may be counterproductive to breastfeeding success. It is important for providers to emphasize the normalcy of weight loss (Flaherman et al., 2012b).

Defecation

Similarly to the first void, the first passage of meconium occurs by an average of 7 hours of age. One-third of newborns pass meconium before their first feeding. Late preterm newborns tend to pass meconium later than term newborns, and 32% of preterm newborns do not pass meconium within 48 hours after birth. Although intake is not well correlated with meconium output, the number of wet and soiled diapers does reflect adequacy of breast milk production by day 4. Fewer than four soiled diapers on day 4 correlates with inadequate milk production (Nommsen-Rivers et al., 2008). By 2 weeks of age, breastfed newborns pass feces more frequently than bottlefed newborns; they also have larger variability in the time between bowel movements (Sievers et al., 1993; den Hertog et al., 2012). After the first month, breastfed and formula-fed infants have about the same rate of defecation.

Because 99.7% of healthy newborns pass meconium by 34 hours of age, those whose passing of meconium is delayed beyond that time deserve extra vigilance during examination to avoid obstructions being missed, such as an imperforate anus (Metaj et al., 2003). A baby with abdominal distention or vomiting and delayed stooling deserves evaluation for a possible gastrointestinal tract obstruction.

Jaundice

As many as 60%–84% of newborns develop visual jaundice in the first few days after birth (Bhutani et al., 2013a; National Institute for Health and Clinical Excellence, 2016). Despite this almost ubiquitous nature, there are few conditions in newborns that create as much controversy and clinician and parental angst as hyperbilirubinemia. Since the discovery of phototherapy in 1956 and its integration into medical care in the 1970s, the standard management of neonatal jaundice in the United States has gone through three distinct phases. Until the early 1990s, clinicians visually monitored term neonates during their 2–5-day newborn nursery stay and obtained serum bilirubin levels on those with significant jaundice. Phototherapy was initiated when the total serum bilirubin (TSB) level reached 15 mg/dL, and an exchange transfusion was indicated if the level rose to 20 mg/dL (Watchko and Oski, 1983). The wisdom of this approach was challenged by reviews of data on jaundice in term newborns without hemolytic disease indicating that the risk of kernicterus in such newborns was extraordinarily low (Watchko and Oski, 1983; Newman and Maisels, 1992).

On the basis of this evidence a “kinder and gentler” approach to the management of hyperbilirubinemia in term newborns was advocated, leading to the AAP practice parameter in 1994 (Provisional Committee for Quality Improvement and Subcommittee on Hyperbilirubinemia, 1994). Under this guideline, phototherapy for a healthy, 72-hour-old term newborn was not definitively recommended unless the TSB level was 20 mg/dL or greater. Unfortunately, publication of this guideline coincided with a shortening of the nursery stay by term newborns to as little as 24 hours. Thus newborns were discharged home before their bilirubin levels “peaked” at 3–4 days, and there were numerous reports of newborns with extremely high bilirubin levels and a general

• **Fig. 26.4** “Bhutani nomogram” for total serum bilirubin levels in newborns born at 36 weeks’ gestation or later. (Modified from Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischARGE hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6–14.)

impression that the incidence of kernicterus was increasing as well. In retrospect, it does not appear that the incidence of kernicterus did increase, but case reports and anecdotal evidence led to significant consternation by clinicians, parents, and quality assurance organizations (Burke et al., 2009; Brooks et al., 2011).

Since newborns are usually discharged well before their bilirubin levels reach their peak, it was clear that predictive models were needed to assess risk in newborns who are discharged early. Bhutani et al. (1999) developed a nomogram based on data from neonates in whom serum bilirubin levels were measured multiple times (Fig. 26.4). Those newborns who had initial bilirubin levels above the 95th percentile at any time point (in hours) were more likely to have “significant hyperbilirubinemia” when the levels were measured subsequently than those with lower levels initially. These data were used in the development of the 2004 AAP practice guideline (American Academy of Pediatrics Subcommittee on Hyperbilirubinemia, 2004). With this iteration of the guideline, clinicians are provided hour-by-hour guidance on TSB levels for which phototherapy or exchange transfusion is indicated. Separate curves for “low-risk,” “medium-risk,” and “high-risk” neonates have been developed on the basis of the presence of factors (e.g., GA less than 38 weeks, hemolytic disease, serum albumin level less than 3.0 g/dL, glucose 6-phosphate dehydrogenase deficiency, sepsis, and acidosis) that might increase the risk of brain damage in an neonate who has an extremely high TSB level (Maisels et al., 2009). Internet-based tools are available in which the appropriate management for a newborn with a specific bilirubin level at a specific hour after birth is provided.

There are numerous neonatal conditions that increase the risk of hyperbilirubinemia (Dennerly et al., 2001). Chief among these is hemolysis secondary to maternal antibodies to red blood cell

antigens. Although hemolysis secondary to antibodies to Rh factor is now quite rare in the United States and other high-income countries because of proper management of Rh-negative mothers, it has been estimated that as many as 114,000 newborns die each year in locations in the world where resources are not adequate to prevent Rh sensitization (Bhutani et al., 2013b). A common cause of hemolysis in newborns is an ABO incompatibility. Since there is no way to prevent hemolysis from an ABO incompatibility, it may be useful to test umbilical cord blood from neonates born to mothers with blood type O for blood type and the presence of antibodies on their red cells (i.e., Coombs test) at birth. The increase in bilirubin level secondary to ABO compatibility, even with a positive direct Coombs test, is highly variable. Some newborns will have an early and dramatic rise in serum bilirubin level and evidence of hemolysis, while in others no effect can be detected clinically. In addition to ABO incompatibility, some women will have antibodies to “minor” red cell antigens that can usually be diagnosed prenatally. In most instances the increases in bilirubin level associated with antibodies against minor antigens are mild.

Other neonatal conditions that are risk factors for hyperbilirubinemia include bruising secondary to birth trauma and polycythemia. Decreased intake of breast milk may lead to decreased passage of stool. Because intestinal bacteria break down conjugated bilirubin to the unconjugated form, a decrease in stool frequency may lead to increased reabsorption of this unconjugated bilirubin (enterohepatic circulation). Breastfeeding is a significant risk factor for hyperbilirubinemia particularly when intake is limited. The propensity for developing significant jaundice is variable in different racial groups. Asian and Native American newborns are at the highest risk of significant hyperbilirubinemia (Dennerly et al., 2001).

Finally, late preterm newborns are at significantly increased risk of both significant hyperbilirubinemia and kernicterus.

Traditionally, visual assessment has been used to judge whether or not a newborn has significant jaundice. Unfortunately, visual assessment is only relatively accurate; reported correlations between estimated bilirubin levels and TSB levels are in the range of 0.36–0.75, and clinicians tend to underestimate the severity of newborn jaundice ([National Institute for Health and Clinical Excellence, 2016](#)). Because of this, it is recommended that all newborns be screened for jaundice before discharge from the birth hospitalization with a TSB level or a transcutaneous bilirubin (TcB) measurement using a transcutaneous bilirubinometer, a noninvasive method for estimating bilirubin levels ([Maisels et al., 2009](#)).

Although TcB level offers a reasonable approximation of the gold standard TSB level, with published correlations ranging from 0.77 to 0.93, it is designed to be used only as a screening tool ([Maisels et al., 2009](#); [National Institute for Health and Clinical Excellence, 2016](#)). If the TcB level is above a certain threshold, it is recommended that blood be obtained for a TSB measurement to be used for clinical decision making. Several decision rules have been recommended for use in newborns during their birth hospitalization. These include:

1. Plot TcB level results on the Bhutani nomogram. If the TcB level is in the high-intermediate or high-risk zone, the screen is “positive.”
2. Determine the phototherapy threshold with use of the AAP hyperbilirubinemia guideline. If the TcB level is within 70% of this threshold, the screen is positive.
3. Determine the phototherapy threshold. If the TcB level is within 3 mg/dL of this threshold, the screen is positive ([Maisels, 2006](#); [Maisels et al., 2009](#)).

With each of these rules it is recommended that a TSB level be obtained in a newborn with a positive TcB screen. The utility of these three decision rules has been evaluated in a large multisite study ([Taylor et al., 2016](#)). The main outcome was accurate identification of a newborn with a TSB level at or above the phototherapy threshold. The false-negative rates with each of the rules was less than 10%, but no rule correctly identified all neonates with a TSB level requiring phototherapy. These results indicate that use of TcB level for screening is not foolproof; a blood draw for a TSB level may be needed if clinical evaluation suggests that the level of jaundice in a neonate is more severe than that indicated by TcB measurement.

Unless levels are high enough to require an exchange transfusion, phototherapy is effective for treatment of a newborn with significant hyperbilirubinemia. Although repeated measurements of direct bilirubin level are not cost-effective, one assessment is helpful before, or just after, initiation of phototherapy to rule out direct hyperbilirubinemia ([Newman et al., 1991](#)). An assessment of the potential for hemolysis as the cause of the elevated bilirubin level, possibly including a review of maternal and infant blood type, direct Coombs test result, hematocrit, reticulocyte count, and red cell morphology, may also be useful.

There is no conclusive evidence as to whether continuous phototherapy leads to more rapid reduction in serum bilirubin levels than intermittent treatment ([Lau and Fung, 1984](#); [American Academy of Pediatrics Subcommittee on Hyperbilirubinemia, 2004](#); [Sachdeva et al., 2015](#)). Unless bilirubin levels are approaching exchange transfusion levels, it is probably reasonable to discontinue treatment for several minutes to 1 hour at frequent intervals to allow parents to feed and hold their baby. Serial bilirubin measurements are needed to determine the adequacy of therapy and to

determine when phototherapy can be discontinued. A “rebound” bilirubin level obtained 24 hours after discontinuation of phototherapy may be helpful in some clinical situations.

Respiratory Complications

The term or late preterm fetus accomplishes transition from dependency on the placenta to the newborn cardiorespiratory system, for the most part, without incident. After birth, pulmonary blood flow increases, fetal shunts reverse and begin to close, spontaneous breathing effort is initiated, and fetal lung fluid is cleared. Effective cardiorespiratory function, as represented by an absence of respiratory distress (nasal flaring, grunting, chest wall retractions, a respiratory rate of greater than 60 per minute) and an oxygen saturation in the mid-90s, is established by several hours of age ([Levesque et al., 2000](#); [O'Brien et al., 2000](#)).

This normal sequence of events fails to occur in 2%–8% of newborns born at 34 weeks' gestation or later ([Hansen et al., 2008](#); [Yoder et al., 2008](#); [Farchi et al., 2009](#)). It is important to keep in mind that the initial presenting symptoms are relatively nonspecific. [Agrawal et al. \(2003\)](#) studied a large number of consecutively born neonates in an attempt to determine the frequency and nature of different early-onset respiratory disorders, and found that more than half of the cases did not meet specific diagnostic criteria. When confronted with early-onset respiratory symptoms, the most important diagnostic considerations to consider include:

- Complex structural cardiac system anomalies; incidence estimated to be between 0.11% and 0.17%; often, but not always, identified by in utero imaging studies ([Oster et al., 2013](#))
- Diaphragmatic hernia; incidence estimated to be between 0.04% and 0.08%; commonly identified by second trimester ultrasound examination ([de Buys Roessingh and Dinh-Xuan, 2009](#))
- Respiratory distress syndrome (RDS); incidence estimated to range between 0.45% and 2.4% depending on the population studied; risk is increased in late preterm newborns and newborns born by cesarean delivery particularly if this happens before labor ([Bertin et al., 1996](#); [Yoder et al., 2008](#); [Jain et al., 2009](#))
- Persistent pulmonary hypertension of the newborn; incidence between 0.1% and 0.3%; often occurs in association with other acute respiratory conditions; a recent large study suggests a slightly increased risk with maternal selective serotonin reuptake inhibitor treatment ([Konduri and Kim, 2009](#); [Huybrechts et al., 2015](#))
- Meconium aspiration syndrome; incidence reported to range between 2% and 9% among newborns delivered through meconium-stained amniotic fluid (7%–20% of all deliveries); risk is increased in newborns delivered after 40 weeks' gestation and/or with intrapartum distress (routine tracheal intubation to facilitate suction is no longer recommended) ([Liu and Harrington, 2002](#); [Bhutani, 2008](#); [Perlman et al., 2015](#))
- Spontaneous pneumothorax; incidence between 0.1% and 0.8%; newborns born by cesarean delivery may be at increased risk ([Zanardo et al., 2007](#); [Benterud et al., 2009](#))
- Transient tachypnea of the newborn (TTNB); incidence ranges between 0.3% and 3.9%; risk factors include late prematurity and cesarean delivery; initial diagnosis is sometimes difficult to differentiate from pneumonia and early respiratory distress ([Gugliani et al., 2008](#); [Yoder et al., 2008](#); [Jain et al., 2009](#); [Tita et al., 2009](#))
- Pneumonia; incidence difficult to determine, one recent retrospective report estimated it to be 0.3%; risk factors include maternal chorioamnionitis and prolonged rupture of membranes;

sometimes it is difficult to differentiate it from RDS and/or TTNB (Yoder et al., 2008)

Review of the maternal history, particularly pregnancy, labor, and delivery, may provide useful diagnostic information. For example, the results of a second trimester ultrasound examination could reveal the possibility of a cardiac defect or diaphragmatic hernia. A positive maternal GBS test result without adequate treatment, prolonged rupture of amniotic membranes, and/or evidence of chorioamnionitis suggests the possibility of pneumonia. For newborns with respiratory distress born by cesarean delivery before the onset of labor a diagnosis of RDS should be considered and GA should be estimated. Finally, TTNB is a diagnosis of exclusion; it is prudent to rule out other causes before this is considered to be the cause of respiratory distress in a term neonate.

In most cases, minimum initial diagnostic efforts for a term newborn with unsuspected respiratory distress should include a chest X-ray and assessment of the arterial oxygen saturation. The results of these studies, in combination with the maternal history, should provide information helpful to (1) establish the initial management, such as the need for supplemental oxygen and/or continuous monitoring, (2) determine the need for further work-up or treatment, possibly including an echocardiogram, laboratory testing, and treatment for possible sepsis, or (3) in severe cases, refer the newborn for further specialty consultation and/or intensive care.

Cardiovascular Issues

Congenital heart disease is a relatively common condition in newborns, with an estimated incidence of 81 cases per 10,000 live births (Reller et al., 2008). Ventricular septal defect (VSD) is, by far, the most common defect, accounting for more than 30% of all cases. The increasing accuracy of prenatal ultrasound examinations has greatly improved the early diagnosis of complex congenital heart disease (CHD). The results of population-based reviews indicate that the sensitivity of routine prenatal ultrasound examinations in identifying selected congenital defects is as high as 70% and is as high as 85% for hypoplastic left-sided heart syndrome (Rasiah et al., 2006; Chew et al., 2007). For mothers at high risk of delivering a newborn with CHD, the use of fetal echocardiography is helpful for delineating the anatomy and significance of specific lesions. However, many of the most common defects, particularly VSD, are not typically detected prenatally.

In the absence of a prenatal diagnosis, detection of CHD is via physical examination and oxygen saturation screening (see the section entitled “Screening for Critical Congenital Heart Disease”). Even if the oxygen saturation screen is normal, it is important to continue to consider the possibility of CCHD since some lesions, particularly coarctation of the aorta, may not be detected with screening (Lannering et al., 2015).

At birth, many babies have loud murmurs that are thought to be from either a closing ductus arteriosus or tricuspid regurgitation (Silberbach and Hannon, 2007). These murmurs are transient and not indicative of disease. Conversely, murmurs associated with VSDs may not be heard for several days, when the pulmonary vascular resistance has dropped enough to permit a significant shunting of blood from left to right. Although the ratio of pathologic to benign murmurs is higher in newborns than in older children, most of the murmurs heard during the newborn nursery stay in a healthy neonate are not clinically significant. Characteristics that increase the likelihood that a murmur signifies the presence of CHD include an intensity of 0.5 or more, a harsh quality, occurrence

during all of systole or into diastole, and being heard best at the lower sternal border or right upper border (Mackie et al., 2009). In a healthy newborn the most common presentation of CHD is a somewhat harsh systolic murmur that is heard best at the lower left sternal border in an asymptomatic newborn, indicative of a VSD.

In addition to auscultation, it is helpful to assess a newborn with a murmur for dysmorphic features and/or other anomalies as these findings increase the likelihood that the murmur is indicative of CHD. It is important to evaluate the adequacy of femoral pulses to rule out coarctation of the aorta. Femoral pulses may be hard to feel in a neonate; if there is uncertainty, upper and lower extremity blood pressures can be measured. Chest radiographs and electrocardiograms are usually of limited value in evaluating healthy newborns with murmurs (Oeppen et al., 2002; Mackie et al., 2009).

Term neonates frequently have alterations in cardiac rhythm and rate. Heart rates in term newborns may be as high as 200 beats per minute (particularly when agitated) or as low as 80 beats per minute (particularly when asleep). These values are usually indicative of normal variation and are not clinically meaningful unless there are other signs of illness and/or if there is a lack of variability in rate with stimulation or attempts at calming the newborn. Arrhythmias are also not uncommon, occurring in approximately 1% of newborns (Southall et al., 1981). By far the most common arrhythmia in a well-appearing term newborn is from premature atrial contractions (PACs) (O'Brien et al., 2000; Larmay and Strasburger, 2004). These are almost always benign and usually transient. If there is concern about an irregular rhythm in a newborn, an electrocardiogram can be obtained. With PACs the irregular beat is initiated by a P wave. Although the QRS complex may be widened, it is always preceded by the P wave. In most cases no further work-up is needed. Cardiology consultation may be warranted if PACs are persistent or if widened QRS complexes are seen on the electrocardiogram.

Possible Neonatal Sepsis

Although early-onset sepsis (EOS) is a distinctly rare occurrence in term neonates, early identification of a newborn with EOS is a central focus of newborn care and a source of considerable anxiety for clinicians. This anxiety is driven by two unique features of EOS. First, the phenomenon of an apparently healthy newborn becoming moribund from overwhelming sepsis in a matter of hours is well described. Secondly, the earliest signs of infection are frequently subtle and nonspecific. Fortunately, with the advent of screening mothers for GBS colonization prenatally and providing intrapartum antibiotics for those colonized, the rates of EOS have fallen substantially in the past 25 years. In the 1980s and 1990s the rates of neonatal sepsis in the United States were estimated at 2.0–2.5 cases per 1000 live births. By 2008 the overall rate was estimated at 0.8–1.0 cases per 1000 live births (Isaacs et al., 1995; Cordero et al., 2004; Stoll et al., 2011; Weston et al., 2011).

The rate of EOS is lower among term newborns. In one large surveillance study, conducted in the era of nearly universal screening for maternal GBS infection, the rate of sepsis in newborns with birthweights greater than 2500 g was 0.57 cases per 1000 live births (Stoll et al., 2011). However, even with the reduction of GBS cases, this bacterium accounted for most cases of EOS in newborns with birthweights of 2500 g or greater, with a rate of 0.37 cases per 1000 live births. The rate of EOS caused by *Escherichia coli* among newborns with birthweights greater than 2500 g was 0.07 cases per 1000 live births, with the remainder of cases caused

by a variety of other bacteria. Of note, in this study, among a group of almost 400,000 newborns, only two cases of EOS caused by *Listeria monocytogenes* were identified.

Given the current rates of EOS and distribution of pathogens, the decision of whether to initiate empiric antibiotic therapy for possible EOS in a term newborn is dependent on a few key variables. The easiest of these variables to quantify are the maternal GBS screening results, the drugs used, and the timing of intrapartum antibiotic therapy provided to mothers who screen positive. In addition to GBS status, other “risk factors” related to labor and delivery can be used to develop a numeric estimate of a newborn’s risk of EOS at birth (Puopolo et al., 2011; Escobar et al., 2014). In some cases the estimated risk of EOS is sufficiently high at birth such that empiric antibiotic therapy for possible sepsis is begun regardless of the appearance of a neonate. In newborns who are not initially treated with antibiotics, clinicians use vital sign, physical examination, and laboratory test findings in combination with the newborn’s estimated risk at birth to determine when to begin empiric antibiotic therapy for EOS. Unfortunately, although the overall appearance of a newborn is said to be the best predictor of EOS, there are only a handful of specific, objective, and evidence-based vital sign and physical examination findings that are useful, and laboratory test results are, disappointingly, of only moderate help. The utility and limitations of these variables are discussed in the following sections

Group B Streptococcus Screening and Intrapartum Antibiotic Prophylaxis

Since the 1970s GBS has been a major cause of neonatal sepsis (Schuchat, 1998). The implementation of intrapartum antibiotic prophylaxis (IAP) to prevent early-onset GBS disease in neonates has been associated with a more than 80% decrease in the rate of infection (Phares et al., 2008; Centers for Disease Control and Prevention, 2016). Recent surveillance data from the United States suggest that the overall rate of EOS caused by GBS is now in the range of 0.25 cases per 1000 live births. Unfortunately, the rates of GBS disease are more than twice as high among African-American neonates in the United States than in newborns of other races (Centers for Disease Control and Prevention, 2016).

The currently recommended strategy to prevent GBS disease is to obtain rectovaginal cultures on all pregnant women at 35–37 weeks’ gestation and to administer IAP with penicillin or ampicillin during labor to those colonized with the bacteria. In situations where the mother’s GBS status is unknown before the onset of labor, IAP is advised for those with certain risk factors for neonatal infection. IAP is not needed in women who undergo cesarean delivery before the onset of labor with intact amniotic membranes (Verani et al., 2010).

The effectiveness of IAP in preventing early-onset GBS disease in neonates born to colonized mothers is dependent on the drugs used and the timing of administration. Penicillin or ampicillin, with at least one dose given more than 4 hours before delivery, is the most effective treatment. It is estimated that the efficacy of this regimen in preventing GBS disease in term newborns is 91% (95% confidence interval 63%–98%). Although ampicillin or penicillin administered less than 4 hours before delivery has been shown to be effective in reducing vertical transmission, in one surveillance study the effectiveness of ampicillin or penicillin administered less than 2 hours before delivery in preventing early-onset GBS disease was only 47%, and the effectiveness of a dose administered more than 2 hours but less than 4 hours before delivery was estimated at 38%. The effectiveness of clindamycin,

administered to women who had a history of penicillin allergy, was estimated at 22%, although antimicrobial susceptibility testing was infrequently performed on the GBS strains cultured from the mothers in this study (Fairlie et al., 2013). It is recommended that clindamycin be used only for IAP in mothers who are colonized by a strain of GBS that is documented to be sensitive to this antibiotic (Verani et al., 2010). Although there are fewer data on the effectiveness of cefazolin for IAP, on the basis of its pharmacologic profile it is likely to have an effectiveness similar to that of penicillin in preventing GBS disease.

Overall, about 75% of women who are screened for GBS are classified as GBS negative (Van Dyke et al., 2009). However, approximately 10% of these classifications are false negatives. Ironically, because of this false-negative rate, and since mothers with negative GBS screening results do not commonly receive IAP, more than 60% of newborns in the United States who develop early-onset GBS disease are born to women classified as GBS negative (Van Dyke et al., 2009). Thus although the risk of EOS from GBS is very low, clinicians should consider this possibility in term newborns born to “GBS-negative” mothers who are displaying signs and symptoms of the disease.

Term newborns whose mothers have received IAP for a positive GBS screen at least 4 hours before delivery (termed *adequate* IAP) can be safely discharged at 24 hours of age if there are no signs or symptoms of infection (Verani et al., 2010). One area of consternation is how long to observe term newborns when the only doses of antibiotics were administered less than 4 hours before delivery (“inadequate” IAP). Most newborns with sepsis present early in life—many at birth, and nearly all by 12 hours of age (Escobar et al., 2000). Among a group of 172 term newborns with documented early-onset GBS infection, 95% had presenting symptoms within 24 hours after delivery (Bromberger et al., 2000). There is the theoretical concern that newborns whose mothers receive some but inadequate IAP to prevent early-onset GBS disease will have a delayed or muted initial presentation because of the antibiotics received. Perhaps because of this concern, in current guidelines it is recommended that such newborns be monitored in the hospital for at least 48 hours after birth (Verani et al., 2010). However, evidence to date suggests that newborns who develop GBS disease despite IAP, either inadequate or adequate, continue to present within the first 24 hours of life and have the same presentation as those with EOS caused by GBS whose mothers did not receive IAP (Bromberger et al., 2000). These data suggest, but do not definitively indicate, that some term newborns born to GBS-positive mothers who received IAP less than 4 hours before delivery may be discharged at less than 48 hours of age. This decision is best made on an individual basis considering all risk factors, examination of the baby, vital sign stability, the results of any available laboratory tests, and parental wishes.

Evaluation of Perinatal Risk Factors

Because the initial signs and symptoms of EOS can be difficult to distinguish from normal newborn variation, the estimate of a newborn’s risk of sepsis at birth is crucial for determining appropriate monitoring, laboratory testing, and/or treatment. Several prenatal and perinatal conditions are known to substantially increase the chance that a newborn will develop EOS, including preterm birth, prolonged rupture of amniotic membranes, maternal GBS infection and IAP, maternal fever, chorioamnionitis, and history of a sibling with EOS (Verani et al., 2010; Wortham et al., 2016). In particular, the clinical diagnosis of chorioamnionitis may increase the risk of EOS by twofold to sixfold (Benitz et al., 1999; Escobar et al.,

2000). Because of this, both the Centers for Disease Control and Prevention and the AAP recommend blood cultures be obtained and *all* newborns born to mothers with diagnosed chorioamnionitis be treated with empiric intravenous antibiotics pending the results of the blood cultures.

However, guideline recommendations to initiate treatment with intravenous antibiotics on all *term* newborns born to women with chorioamnionitis remain controversial. Many of the large studies that documented the increased risk of EOS in the setting of chorioamnionitis were conducted before universal GBS screening and IAP (Taylor and Opel, 2012). Although exact figures are elusive, it is estimated that chorioamnionitis complicates approximately 3% of births in the United States (Verani et al., 2010). Given the low current rate of EOS, it has been estimated that 80–210 newborns born to mothers with chorioamnionitis would require empiric antibiotic treatment in order to “catch” one neonate with EOS (i.e., the number needed to treat is 80–210). For term newborns who appear well, the estimated number needed to treat is 450 (Wortham et al., 2016).

Investigators from Boston and northern California have adopted a different approach for estimating the risk of EOS at birth in newborns born at 34 weeks’ gestation or later. Using data from more than 600,000 deliveries, they developed a model for assigning a numeric risk of EOS in a newborn based on the following criteria: GA, maximal maternal temperature during labor, hours of rupture of membranes, GBS screening results in the mother, and use and timing of IAP (Puopolo et al., 2011). Of note, the specific presence or absence of chorioamnionitis is not a variable considered in the model. Using a website (<http://www.newbornsepsiscalculator.org>), clinicians can enter the appropriate data for these variables, and a numeric estimate of sepsis at birth in a particular newborn is provided. The risk of sepsis is further refined on the basis of the clinical appearance of the newborn (well-appearing, equivocal presentation, or evidence of clinical illness). Specific criteria for these classifications are provided. The estimated risk for newborns in each of these categories is provided. The clinician can then consider this risk estimate and determine the appropriate management for the baby. Alternatively, the originators have recommended that empiric antibiotic therapy be initiated if the estimated risk of EOS is 1.54 or more cases per 1000 live births (Escobar et al., 2014). However, there is no rationale for this threshold other than the opinion of the investigators.

Clinical and Laboratory Evaluation

Early identification of a newborn with EOS based on clinical and laboratory findings is difficult. A number of signs and symptoms have been reported to be present in neonates with EOS, including fever, hypothermia, temperature instability, hypotension, lethargy, irritability, pale or mottled skin, cyanosis, apnea, hypoglycemia, acidosis, tachycardia, tachypnea, grunting respirations, nasal flaring, and inspiratory retractions (Escobar et al., 2014; Wortham et al., 2016). Unfortunately, with a few exceptions there has been little investigation on how frequently these signs and symptoms are present early in the course of EOS in term newborns, and it is unclear whether the presence of each of these signs and symptoms is more common in those with EOS versus noninfected babies. Thus the utility of most of these signs and symptoms in helping to diagnose EOS is unknown.

It is apparent that most newborns with EOS have clinical signs of illness and that the rate of EOS is significantly lower in well-appearing neonates who are at risk of infection because of maternal and/or perinatal risk factors. In a compilation of studies the rate

of EOS among well-appearing term and preterm newborns was 0.04 per 1000 “at-risk” infants versus 2.9% in symptomatic term and late preterm neonates (Benitz et al., 2015). In another study, of 2785 newborns with birthweights greater than 2000 g who underwent a laboratory evaluation for sepsis, the absence of clinical signs of sepsis reduced the risk of EOS by almost fourfold (Escobar et al., 2000).

The developers of the newborn sepsis calculator (described in the previous section) identified four specific and objective clinical signs of sepsis: temperature of 38.0°C or greater or less than 36.4°C; heart rate of 160 or more beats per minute; respiratory rate of 60 or more breaths per minute; and respiratory distress (grunting, flaring, and retractions) (Escobar et al., 2014). Importantly, for one of these signs to be “present” it needs to be identified at least twice, with the two instances separated by more than 2 hours. If one or more of these signs are present in a newborn previously thought to be “well-appearing,” the newborn is not categorized as having “equivocal” examination findings for EOS. This classification system is useful; the sepsis calculator provides different numeric estimations for the risk of sepsis in a newborn with a given risk at birth based on whether the examination findings are normal or equivocal.

Several laboratory test findings, including a low absolute neutrophil count, a high ratio of immature to total neutrophil counts, a high ratio of immature to total neutrophil counts divided by total neutrophil count, and an elevated C-reactive protein level, are statistically associated with an increased risk of EOS (Benitz et al., 1998; Escobar et al., 2000; Newman et al., 2010; Newman et al., 2014). Unfortunately, many, if not most, newborns with EOS have normal laboratory screening test results (Benitz et al., 1998; Escobar et al., 2000; Newman et al., 2010). Further, the negative predictive values of these tests are very high, but since the prevalence of EOS in term newborns, even those with risk factors for sepsis, is low, a normal laboratory test finding, in isolation, is of limited help in aiding clinical decision making.

Newborn Screening

INDERNEEL SAHAI AND HARVEY L. LEVY

KEY POINTS

- Newborn screening (NBS) provides an opportunity for early identification of newborns with disorders in which the clinical complications develop postnatally and may remain undetected before irreversible clinical damage.
- NBS is a “screen,” and individuals should not be labeled as having a disorder before diagnostic testing confirms the condition.
- Once a disorder has been confirmed, however, treatment should be started without delay to prevent irreversible clinical complications.
- False-positives are inevitable; false negatives are possible.
- The clinical spectrum of disorders is wider than expected.
- The disorder detected is not always the one that was sought.
- Numerous methods are used in NBS, ranging from isoelectric focusing to enzymatic assays, tandem mass spectrometry, and high-throughput genomic sequencing.
- Advances in technology result in modifications in the panel of disorders screened and/or the biomarkers analyzed to screen newborns for them.

Newborn screening (NBS) is directed at disorders in which the clinical complications develop postnatally. In metabolic diseases the complications result from biochemical abnormalities that appear after birth, when the infant is no longer protected by fetal–maternal exchange. For example, the infant with phenylketonuria (PKU) has a normal blood phenylalanine level at birth but within a few hours demonstrates hyperphenylalaninemia. The infant with congenital hypothyroidism (CH) is also protected in utero, most likely from placental transfer of maternal thyroxine (T_4). If the hyperphenylalaninemia in PKU is not controlled by diet or the hypothyroidism in CH is not corrected by supplemental T_4 , the infant begins to show signs of developmental delay and subsequently becomes intellectually disabled. If therapy begins during the first few weeks of life, intellectual disability in both disorders is prevented.

PKU was the first metabolic disorder known to benefit from dietary therapy. This fact was established by the mid-1950s. By the late 1950s it was evident that dietary therapy could prevent intellectual disability if initiated in the neonatal period. Detecting PKU in all affected newborns at that early age, before irreversible brain damage occurred, then became the challenge. Meeting this challenge required neonatal screening for a biochemical marker of the disease, which was accomplished in 1962 when Guthrie developed a simple bacterial assay for phenylalanine requiring only

a few drops of blood saturating circles on filter paper (Guthrie and Susi, 1963). Therefore newborns in newborn nurseries could be routinely tested for PKU in blood specimens obtained by the lancing of the heel and the blotting of the drops of blood onto a filter paper card. This filter paper blood specimen (dried blood spot specimen) could be mailed to a central laboratory for PKU testing. An increased concentration of phenylalanine in the specimen indicated PKU in the infant. By the mid-1960s many states had established routine NBS programs for PKU using the Guthrie method. Infants with PKU were identified in larger numbers than anticipated and showed normal development while receiving treatment (O’Flynn, 1992).

The success of PKU screening led to the addition of tests for other metabolic diseases, including galactosemia, maple syrup urine disease (MSUD), and homocystinuria. These additional tests could be performed on the same blood specimen obtained for PKU screening. Within a decade, NBS expanded to include the endocrine disorders CH and congenital adrenal hyperplasia (CAH), the hematologic disorder sickle cell disease, and later biotinidase deficiency, cystic fibrosis, and other diseases.

In 1990, the technology of tandem mass spectrometry (MS/MS) was applied to the dried blood spot specimen, opening a new era in NBS (Millington et al., 1990; Levy, 1998). This method allowed the accurate detection of numerous biochemical markers for metabolic disorders with a single assay, thereby replacing several assays traditionally used in screening for metabolic disorders and adding additional biomarkers not detectable by previous methods, thus greatly expanding the spectrum of conditions identifiable in the neonate (Levy and Albers, 2000). By the early 1990s, Naylor (Chace and Naylor, 1999) and Rashed et al. (1995) began using MS/MS to routinely screen neonates for more than 20 biochemical disorders with high specificity that resulted in an extremely low rate of false-positive results. Currently all programs in the United States and many screening programs in Europe and elsewhere have integrated MS/MS into NBS; some are screening newborns for more than 60 individual conditions (<http://www.babysfirsttest.org/newborn-screening/states>).

In 2006, in an attempt to standardize screening panels nationwide, the American College of Medical Genetics (2006) recommended a panel of 29 core conditions for screening and an additional 25 secondary conditions for which test results could be reported. These secondary conditions, are those that are identified in the course of screening for the 29 core conditions, but either their clinical spectrum is not well known or effective treatment is unavailable. Currently the task of reviewing and recommending

conditions nominated for inclusion in the Recommended Uniform Screening Panel (RUSP) is performed by the Advisory Committee on Heritable Disorders in Newborns and Children. The committee completes a systematic evidence-based review, deliberates on the evidence available, and votes to recommend or not recommend adding the nominated condition to the RUSP for consideration by the Secretary of Health and Human Services. The secretary makes the final decision on whether to add, or not to add, a recommended condition to the RUSP. At time of writing the RUSP includes 34 core disorders and 26 secondary disorders (Tables 27.1–27.2) (<http://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/recommendedpane/>).

Molecular diagnostic techniques (i.e., DNA analysis) are also used in NBS, predominantly as “second-tier” tests to specify diseases such as cystic fibrosis (CF) or medium-chain acyl-coenzyme A (CoA) dehydrogenase deficiency (MCADD) that are suspected because of a primary screening abnormality. Molecular testing substantially increases the positive predictive value of a primary screening result based on metabolite testing (Ranieri et al., 1994; Wilcken et al., 1995; Ziadeh et al., 1995). With the initiation of screening for severe combined immunodeficiency (SCID) syndrome, wherein the markers measured are DNA molecules (i.e., T-cell receptor excision circles [TRECs]), the role of molecular technology extended into primary marker analysis (Vogt, 2008; Baker et al., 2009). The use of molecular testing in screening will most likely expand further with advances in DNA technology.

Screening Procedure

Currently almost all disorders on the RUSP are screened by laboratory analysis of the dried blood spot specimen of the neonate. The two exceptions are a point-of-care hearing test and pulse oximetry performed in the nursery to screen newborns for hearing loss and critical congenital heart disease (CCHD) respectively.

Specimen

The blood specimen is generally obtained from the heel of the infant. This simple sampling method, conceived and introduced by Guthrie and Susi (1963), has made NBS feasible, since blood is easily obtained and can be easily and inexpensively delivered to a central testing facility by mail or courier. There are no serious complications from obtaining these newborn specimens, contrary to early fears that their collection would lead to infection or result in excessive bleeding.

Specimen Collection

The blood specimen should be obtained from the lateral or the medial side of the heel (Fig. 27.1). Blood should be applied to only one side of the filter paper card, but it should saturate each circle on the card. Contamination of the filter paper specimen with iodine, alcohol, petroleum jelly, stool, urine, milk, or a substance such as oil from the fingers can adversely affect the results of the screening tests. In addition, exposure to heat and humidity can inactivate enzymes and produce false results. The specimen should be dried in air at room temperature for at least 3 hours before being placed in an envelope.

Specimens are sometimes collected in capillary tubes, by venipuncture of a dorsal vein or from a central line, and then spotted on filter paper. There is little or no substantial difference in analyte levels between blood collected directly from the heel

• **Fig. 27.1** Hatched areas on the medial and lateral sides of the heel of the sole indicate the proper sites for a heel stick in the newborn.

and that collected by any of these other methods (Lorey and Cunningham, 1994). However, there is the danger of introducing amino acids into the specimen in infants receiving total parenteral nutrition (TPN) if the blood is collected from a central line, resulting in a false-positive increase in the levels of amino acids or interference in some molecular assays by the heparin within the line. In general, it is preferable that blood for screening be spotted on filter paper directly from the heel.

Timing of Collection

Specimen collection timings differ around the world. In the United States most specimens are collected 24–48 hours after birth. In Europe and Australia, however, screening specimens are collected within 48–72 hours, and in the United Kingdom the specimen is not collected until the newborn is 5–8 days old (Public Health England, 2013). The specimen should be obtained from every newborn before nursery discharge or by the third day of life, whichever is first. In newborns whose initial specimen was obtained within the first 24 hours after birth, as may happen with the practice of early nursery discharge, a second blood specimen should be obtained at no later than 7 days of age to be certain that a diagnosis is not missed.

NBS encompasses a gamut of conditions, each with its own ideal screening period during which there is the greatest chance of diagnosing the disorder and before the onset of symptoms. As a result, it is worth noting that recommendations on the timing of specimen collection, although appropriate for most conditions, may not be ideal for all conditions on the screening panel. For instance, for CAH, in which the symptoms can manifest themselves within the first week of life, the optimal time for collection of the specimen is within 24–48 hours after birth. Formerly there was concern that with the NBS specimen collected early, often during the first day of life, some newborns with metabolic disorders or with CH might not have a sufficient degree of abnormality for identification. However, the MS/MS method with its increased sensitivity and specificity has considerably increased the reliability of screening for metabolic conditions in very early specimens (Chace and Naylor, 1999). Furthermore, use of thyroid-stimulating

**TABLE
27.1****Core Disorders in the Recommended Universal Screening Panel**

| Disorder | Acronym | Primary Marker |
|--|----------|---------------------------------------|
| Metabolic Disorders Detected by Tandem Mass Spectrometry (Amino Acid and Acylcarnitine Markers) | | |
| Organic Acid Disorders | | |
| β-Ketothiolase deficiency (mitochondrial acetoacetyl-CoA thiolase deficiency) | BKT | C5:1 |
| Cobalamin defects A, B, | CBL A,B | C3 |
| Isovaleric acidemia ^a | IVA | C5 |
| Glutaric aciduria I | GA-I | C5DC |
| 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency ^a | HMG | C5OH |
| Multiple carboxylase deficiency ^a | MCD | C3; C5OH |
| 3-Methylcrotonyl-CoA carboxylase deficiency | 3MCC | C5OH |
| Methylmalonic acidemia (mutase) ^a | MMA-MUT | C3 |
| Propionic acidemia ^a | PA | C3 |
| Fatty Acid Oxidation Defects | | |
| Carnitine uptake defect (carnitine transporter defect) | CUD | C0 (reduced) C0 |
| Long-chain hydroxyacyl-CoA dehydrogenase deficiency ^a | LCHAD | C16OH/C18:1OH |
| Trifunctional protein deficiency ^a | TFP | C16OH/C18:1OH |
| Medium-chain acyl-CoA dehydrogenase deficiency | MCAD | C8 |
| Very long chain acyl CoA dehydrogenase deficiency | VLCAD | C14:1 |
| Amino Acid Disorders | | |
| Argininosuccinic aciduria (argininosuccinate lyase deficiency) ^a | ASA | Argininosuccinic acid |
| Citrullinemia I (argininosuccinate synthase deficiency) ^a | CIT-I | Citrulline |
| Phenylketonuria | PKU | Phenylalanine |
| Maple syrup urine disease ^a | MSUD | Leucine |
| Homocystinuria | HCY | Methionine |
| Tyrosinemia type I | TYRI | Succinylacetone |
| Other Metabolic Disorders | | |
| Biotinidase deficiency | BIOT | Biotinidase activity |
| Galactosemia ^a | GALT | Total galactose, GALT activity |
| Glycogen storage disease type II (Pompe disease) | GSD-II | Lysosomal acid α-glucosidase activity |
| Mucopolysaccharidosis type I | MPS-I | α-L-Iduronidase activity |
| X-linked adrenoleukodystrophy | X-ALD | C26:0 lysophosphatidylcholine |
| Endocrine Disorders | | |
| Congenital adrenal hyperplasia ^a | CAH | 17-Hydroxyprogesterone |
| Congenital hypothyroidism | CH | T ₄ , TSH |
| Hemoglobin Disorders | | |
| S,S disease (sickle cell anemia) | HbSS | Hb variants |
| S,C disease | HbS/C | Hb variants |
| Hemoglobin S/β-thalassemia | HbS/β-Th | Hb variants |
| Other Disorders | | |
| Cystic fibrosis | CF | Immunoreactive trypsinogen |
| Severe combined immunodeficiency | SCID | T-cell receptor excision circles |
| Hearing | HEAR | Failed hearing test |
| Critical congenital heart disease | CCHD | Pulse oximetry |

Hb, Hemoglobin.

hormone (TSH) as the primary marker for CH, or as a second-tier test when T_4 is the primary marker, has similarly allowed early screening for CH to be reliable.

Special circumstances require specific attention to newborn blood specimen collection. Premature newborns or those with very low birth weight, as well as newborns who are sick and those in neonatal intensive care units (NICUs), are at risk of unreliable screening owing to factors such as the unique physiology of the newborn, therapeutic interventions, and a focus on critical activities in caring for the very sick neonate. Consequently, a single specimen is inadequate for screening newborns in this subpopulation, and

additional specimens should be collected for retesting. Serial screening with collection of three specimens—on admission to the NICU, between 24 and 48 hours after birth, and at discharge or at 28 days of age, whichever is sooner—has been proposed as an adequate and efficient protocol for this population ([Clinical and Laboratory Standards Institute, 2009](#)). In addition, some programs recommend that screening be performed every month until discharge for babies who continue to remain in the NICU.

A blood specimen should be collected from any infant who is being transferred to a different hospital or to an NICU, regardless of age. The first specimen should be collected before transfer, and

a second specimen should be collected at the receiving hospital by 4 days of age. This dual collection policy covers the child from whom a newborn specimen might not have been obtained in the turmoil that frequently accompanies the transfer of neonates.

In a newborn who is to receive a blood transfusion within 24 hours of birth precluding collection of an ideal routine specimen, a screening specimen should ideally be collected before transfusion, and a second specimen should be collected 2 days after the transfusion. In addition, a third screening specimen should be obtained 2 months after the last transfusion, when most of the donor red blood cells have been replaced, to ensure reliable testing for analytes present in red blood cells if a pretransfusion specimen has not been obtained.

Screening Tests

NBS tests are usually performed in a centralized state, provincial, or regional laboratory. In a regional program the specimens may be received by the state program and then delivered to the regional state or private laboratory, or they may be sent directly to the regional laboratory. In either case the individual state programs serve as the state data and follow-up centers.

The testing procedure begins with the punching of small discs (each usually 3 mm in diameter) from the screening specimen. These small discs are then analyzed by various methods for the individual markers being sought. Amino acids and acylcarnitines, the markers for most of the screened metabolic conditions, are simultaneously measured by MS/MS (Rinaldo et al., 2004). As implied at the beginning of this chapter, MS/MS is superior in terms of accuracy of measurement of the individual analytes when compared with alternative methods originally used for screening amino acids, such as bacterial assays or fluorometric techniques. Immunoassays, including fluorimmunoassay and enzyme-linked immunosorbent assays, are used to test for endocrinopathies such as CH and CAH, for infectious diseases such as congenital toxoplasmosis, and for cystic fibrosis. Hemoglobin analysis of blood eluted from the filter paper can be performed either by high-performance liquid chromatography (HPLC) or by isoelectric focusing to identify abnormal hemoglobins associated with the hemoglobinopathies sickle cell disease (hemoglobin S) and thalassemia (hemoglobin A₂, hemoglobin H). An enzyme assay is often used to screen newborns for galactosemia and is always used to screen newborns for biotinidase deficiency. A molecular assay (quantitative polymerase chain reaction) is applied to identify SCID by quantifying TRECs, a marker of newly formed, antigenically naïve thymic emigrant T cells (Chan and Puck, 2005). TREC analysis was the first NBS test to use DNA as the primary analyte. Before implementation of screening for SCID, molecular assays were used only as second-tier tests to detect targeted mutations in disorders such as CF following an out-of-range biomarker. Several platforms, DNA microarrays, and microsphere-based assays can multiplex several molecular and immunologic assays for high-throughput screening and are being used by screening programs (McCabe and McCabe, 1999; Dobrowolski et al., 1999; Green and Pass, 2005). Next-generation sequencing (NGS) technologies with their new high-throughput and massively parallel DNA sequencing technologies have substantially reduced the cost and time required for sequencing and have made it possible to sequence the whole exome and entire coding regions of a gene/genes (Landau et al., 2014). NGS has already been adopted by a few screening laboratories to provide supplemental genotyping information as a second-tier test (Baker et al., 2016) and offers the prospect of

becoming a first-tier test to screen newborns for genetic disorders that do not have a biomarker identifiable by current screening (see the section entitled “The Future” at the end of this chapter).

Secondary Tests

An abnormal finding on an NBS test is not diagnostic. Abnormalities in the newborn specimen can be transient or artifactual. Accordingly, when an abnormality is identified, the original specimen is retested for the analyte that was abnormal. Additional tests can be performed by the screening laboratory to substantiate the finding and increase the specificity of screening (Rinaldo et al., 2006; Matern et al., 2007).

In screening newborns for CH, many programs initially measure T₄. Specimens in which a low T₄ level is found are further tested for an increased level of TSH, which would indicate CH. A normal thyroid stimulating hormone (TSH) level suggests transiently low T₄ levels, a common finding in premature infants, or T₄-binding globulin deficiency. Some screening programs have adopted screening protocols in which the primary analysis is for TSH, and T₄ is measured as a second-tier test in specimens with high concentrations of TSH. Similarly, in screening newborns for galactosemia, an elevated galactose measurement in a specimen can trigger the analysis of galactose 1-phosphate uridylyltransferase (GALT) activity as a second-tier test.

Second-tier molecular testing is also performed in some screening laboratories. For example, in screening newborns for cystic fibrosis, an initial out-of-range primary marker prompts DNA analysis to identify several specific pathogenic mutations (Wilcken et al., 1995; Comeau et al., 2004; Rock et al., 2005). Screening programs following this two-tier immunoreactive trypsinogen–DNA approach can identify up to 99% of patients with CF and report a positive predictive value ranging between 1/9.5 and 1/25 (Grosse et al., 2004). Molecular assays to detect disease-causing mutations are currently used as second-tier tests for several other disorders, and their use is likely to expand with advances in DNA technology. Some examples include testing for the prevalent c.985A>G mutation in MCADD screening, a panel of several GALT mutations in galactosemia screening, and sequencing of the *ABCD1* gene in X-linked adrenoleukodystrophy (X-ALD) screening.

The final interpretation of the screening results is based on the primary analysis and, if available, the results of second-tier testing. However, it is important to realize that screening is not intended to be diagnostic; abnormal screening results must be supported by confirmatory investigations. These studies require additional specimens and are performed by clinical laboratories or sometimes by the screening laboratory.

Physician Contact for Abnormal Results

Table 27.3 indicates disorders or other reasons for abnormal screening results, sorted according to the primary analyte usually used to screen the newborn for the condition. For example, a low T₄ level together with an elevated TSH concentration indicates CH, and a marked elevation of 17-hydroxyprogesterone (17-OHP) level indicates the likelihood of CAH. An elevation of an acylcarnitine level could indicate an organic acid or fatty acid oxidation disorder.

Any infant for whom such a screening result is reported should be evaluated by the primary care provider as soon as possible to facilitate the next steps toward the confirmation and management of the disorder. However, several conditions screened for are

**TABLE
27.3****Disorders or Other Reasons for Abnormal Screening Results Sorted by Primary Marker Analyzed**

| Marker | Concentration | Disorders | Possible Causes of False-positives |
|---|---------------|---------------------------------|--|
| Markers Analyzed Using Tandem Mass Spectrometry | | | |
| Free carnitine | Low | CUD | Poor feeding, maternal CUD |
| Free carnitine | High | CPT-I deficiency | Carnitine supplementation |
| Propionylcarnitine | High | MMA, PA, CBL (A, B), CBL (C, D) | Hemolysis, ^a maternal biotin deficiency, carrier of associated disorders |
| Butyrylcarnitine | High | SCADD/EE/IBDD | Hypoglycemia from other causes, ^a FIGLU level elevation |
| Tiglylcarnitine | High | BKT deficiency | VLBW neonate |
| Isovalerylcarnitine | High | IVA | Antibiotics containing pivalic acid, IVA/MBCD carrier, VLBW neonate, neonate receiving total parental nutrition, FAS hemoglobin profile ^a |
| Glutaryl carnitine | High | GA-I | MCADD carrier, twin or multiple births ^a |
| 3-Methylglutaryl carnitine | High | HMG deficiency | Severe respiratory distress, neonates receiving ECMO ^a |
| Hydroxyisovalerylcarnitine | High | 3MCC deficiency | Maternal 3MCC deficiency, maternal biotin deficiency |
| Octanoylcarnitine | High | MCADD | MCADD carrier, MCT supplementation |
| Tetradecenoylcarnitine | High | VLCADD | Carrier |
| Hydroxyhexadecanoylcarnitine | High | LCHADD/TFP | Carrier, renal dysfunction |
| Hexadecanoylcarnitine | High | CPT-II deficiency | Severe hemolysis ^a |
| Arginine | High | Arginase deficiency | Hyperalimentation |
| Argininosuccinic acid | High | ASA | — |
| Citrulline | Low | OTC/CPS/NAGS | Poor feeding ^a |
| Citrulline | High | CIT-I, CIT-II | Carriers |
| Phenylalanine | High | PKU | Hyperalimentation, specimen contaminated with artificial sweetener ^a |
| Leucine | High | MSUD | Hyperalimentation, hydroxyprolinemia (benign disorder) |
| Methionine | High | HCY | Hyperalimentation, liver dysfunction |
| Tyrosine | High | TYR-II | Prematurity, transient immaturity of enzyme |
| Succinylacetone | High | TYR-I | — |
| Markers Analyzed by Assays Other Than Tandem Mass Spectrometry | | | |
| Biotinidase activity | Low | Biotinidase deficiency | Exposure of specimen to heat, improper drying |
| Total galactose | High | Galactosemia | Contamination with milk/cream |
| GALT activity | Low | Galactosemia | Exposure of specimen to heat |
| 17-Hydroxyprogesterone | High | CAH | Physiologic stress (seen commonly in NICU babies), VLBW, EDTA in specimen |
| T ₄ /TSH | Low/high | CH | Neonates in NICU, maternal thyroid medications |
| Immunoreactive trypsinogen | High | CF | VLBW neonate, NICU |
| T-cell receptor excision circles | Low | SCID | Other immunodeficiencies, Di George syndrome, heparin in specimen ^a |
| α-L-Iduronidase | Low | MPS I | Pseudodeficiency |
| Lysosomal acid α-glucosidase | Low | GSD-II | Pseudodeficiency |
| C26:0 lysophosphatidylcholine | High | X-ALD | Zellweger spectrum disorders |

3MCC, 3-Methylcrotonyl-CoA carboxylase; ASA, argininosuccinic aciduria; BKT, β-ketothiolase deficiency; CAH, congenital adrenal hyperplasia; CBL, cobalamin defect; CF, cystic fibrosis; CH, congenital hypothyroidism; CIT-I, citrullinemia I; CIT-II, citrullinemia II; CPS, carbamoyl phosphate synthetase deficiency; CPT-I, carnitine palmitoyltransferase I; CPT-II, carnitine palmitoyltransferase II; CUD, carnitine uptake defect; ECMO, extracorporeal membrane oxygenation; EDTA, ethylenediaminetetraacetic acid; EE, ethylmalonic encephalopathy; FAS, hemoglobin electrophoretic profile indicative of sickle cell trait; FIGLU, formiminoglutamic acid; GA-I, glutaric aciduria I; GSD-II, glycogen storage disease type II; HCY, homocystinuria; HMG, 3-hydroxy-3-methylglutaryl-CoA lyase; IBDD, isobutyryl-CoA dehydrogenase deficiency; IVA, isovaleric acidemia; LCHADD, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency; MBCD, 2-methylbutyryl-CoA dehydrogenase deficiency; MCADD, medium-chain acyl-CoA dehydrogenase deficiency; MCT, medium-chain triglycerides; MMA, methylmalonic aciduria; MPS I, mucopolysaccharidosis type I; MSUD, maple syrup urine disease; NAGS, N-acetylglutamate synthetase deficiency; NICU, neonatal intensive care unit; OTC, ornithine transcarbamylase deficiency; PA, propionic acidemia; PKU, phenylketonuria; SCADD, short-chain acyl-CoA dehydrogenase; SCID, severe combined immune deficiency; T₄, thyroxine; TFP, trifunctional protein deficiency; TSH, thyroid-stimulating hormone; TYR-I, tyrosinemia Type I; TYR-II, tyrosinemia Type II; VLBW, very low birth weight; VLCADD, very long chain acyl-CoA dehydrogenase deficiency; X-ALD, X-linked adrenoleukodystrophy.

^aAssociations observed in the New England Newborn Screening Program.

extremely rare, and primary healthcare professionals might not have sufficient information available to be able to direct appropriate intervention in screen-positive infants. To overcome the challenge, readily accessible, one-to-two page explanations of the possible disorders represented by the abnormality and the recommended confirmatory tests, known as ACTion (ACT) sheets and confirmatory algorithms (Kaye et al., 2006), are available on the website of the American College of Medical Genetics (https://www.acmg.net/ACMG/Publications/ACT_Sheets_and_Confirmatory_Algorithms/ACMG/Publications/ACT_Sheets_and_Confirmatory_Algorithms/ACT_sheets_Homepage.aspx). Similar explanations are also often included with the screening report.

Although all specimens with a metabolite concentration that crosses its threshold are considered screen positive, all screen-positive results are not associated with the same likelihood of being associated with a disorder. Most infants with a positive screening result that is only mildly abnormal are less likely to have a disorder (see the later discussion of false-positive results) than are infants with analyte concentrations that are severalfold above the cutoff. Applying a uniform approach for all positive results in terms of urgency of intervention or a battery of tests suggested can result in unnecessary parental anxiety and medical costs. However, if recommendations for further action and work-up are customized in accordance with the potential significance of the abnormality, both parental anxiety and the costs associated with false-positive results can be reduced. To achieve this goal, some programs subcategorize positive screening results. The New England NBS Program uses primary marker concentrations, second-tier analyses, biomarker profiles for markers analyzed by MS/MS, and acuity of the likely disorder to subcategorize out-of-range screening results (Sahai et al., 2007). The primary care providers are supplied with category-based, customized fact sheets when a positive screening result is reported (Sahai and Eaton, 2008). These sheets include information on disorders associated with the marker, the estimated likelihood of being affected, clinical presentations of likely disorders, factors contributing to false-positives, and recommendations for further management. The follow-up recommendations can range from immediate admission to a hospital, where further evaluation and therapy for the illness can be initiated without delay, to simply repeating the filter paper analysis on a sample collected a few days later. Other programs approach this problem differently, but with the same goal in mind, providing the primary care providers with the information needed to put the result in the appropriate context for the family.

Any infant for whom an abnormal screening result is reported should be seen as soon as possible and evaluated with a careful history and physical examination. When specific guidelines based on the individual results are not provided by the screening program and the infant is ill or the likely disorder manifests itself acutely within the first few days of life (see Tables 27.1–27.2), a specialist should be contacted. The infant may need to be admitted to the hospital, where further evaluation and therapy for the illness can be initiated without delay.

If the infant is active and alert with good feeding and shows no abnormal signs on initial evaluation and the suspected disorder does not require immediate attention, a second filter paper blood specimen can be obtained and sent to the screening laboratory for repeat testing, or confirmatory testing can be performed on a less urgent basis. In many cases, confirmatory testing or referral to a specialist is required only if the second test indicates the presence of a disorder. However, the follow-up of an initial positive screening result can differ. In some programs, more specific confirmatory testing is the first response to a presumptive positive newborn

screen, with a less intense time frame for individuals in whom the level of suspicion is lower.

The physician should contact the screening laboratory when an infant whose screen has been reported as normal or whose screening results have not yet been reported has symptoms that suggest a metabolic disorder. The screening laboratory can check the results in the infant's newborn specimen. If the testing has been completed and the newborn specimen is retained in storage, the laboratory may wish to recover the specimen and repeat the tests. The physician should also contact the screening laboratory for the results of repeated tests and inform the family of the results as soon as possible. If the second result is normal, the duration of the family's anxiety may be shortened.

Screened Disorders

Brief summaries of the categories of the most common disorders detected by NBS are provided in the following sections. There is no attempt to describe any of the disorders in detail or their rare variants.

Metabolic Disorders

Amino Acid Disorders

The amino acid disorders are caused by an enzymatic defect in the catabolic pathway of amino acids, with consequent accumulation of specific amino acids above the block. Screening relies on the detection of these elevated amino acids in the newborn specimen. The clinical manifestations may be a result of the toxic effects of the accumulating amino acid and metabolites produced by alternative pathways, a deficiency of the products of the normal pathway, or both. PKU is the best known example of an amino acid disorder and is the paradigm for screened disorders in the newborn.

In addition to PKU, MSUD and homocystinuria are historically significant in the context of screening because they are among the original metabolic conditions for which screening was performed before the expansion of NBS through the introduction of MS/MS technology. Screening for other amino acid disorders such as the urea cycle defects became possible only with the advent of MS/MS technology.

Phenylketonuria

In PKU the cardinal screening feature is an increased level of phenylalanine. PKU should always be identified by NBS. If untreated, patients with PKU experience severe intellectual disability and other neurologic abnormalities. The average incidence of the disorder is approximately 1 in 12,000 live births. With screening by MS/MS, PKU can reliably be identified as early as the first day of life (Chace et al., 1998). Not all infants with an elevation of phenylalanine level have PKU. Occasionally, an infant with elevated phenylalanine level will have one of the cofactor deficiency (pterin) disorders that can result in severe neurologic disease with choreo-athetosis and seizures as well as profound intellectual disability unless this is diagnosed and treated specifically. Therefore on evaluation every infant with increased phenylalanine level must have a blood and urine test to determine whether a pterin disorder rather than PKU is the diagnosis. Mild phenylalanine level elevations not due to a pterin disorder can indicate mild hyperphenylalaninemia, usually a benign condition. Liver disease, such as that associated with galactosemia, tyrosinemia type I, or citrin deficiency, can also produce increased levels of phenylalanine. For all of these reasons, treatment of PKU should never be started on the basis

of a positive screening test result alone. Every identified infant should be referred directly to a metabolic center for confirmatory testing and prompt consideration of dietary treatment. If the screening level of phenylalanine is only slightly increased, a second NBS specimen could be collected and sent to the screening program to determine whether the first result was persistent or transient before a diagnostic work-up is initiated.

Maple Syrup Urine Disease

The primary indicator for MSUD in the newborn blood specimen is an increase in leucine level. To increase the specificity for MSUD of an abnormal leucine measurement, some screening programs also report the ratio between leucine and a reference amino acid or alloisoleucine analysis as a second-tier test (Matern et al., 2007). The average incidence of classic MSUD is 1 in 185,000. MSUD can be a fulminant disease presenting initially with nonspecific findings such as vomiting, irritability, and lethargy, and it can progress rapidly to coma and death. Consequently, the finding of a substantially increased leucine level in the newborn blood specimen should prompt an immediate telephone call from the screening program to the attending physician. If the infant is sick, he or she should be transported immediately to a NICU at a medical center with a metabolic specialist. Confirmatory plasma and urine specimens should be obtained, and emergency therapy should be initiated. Plasma amino acid analysis in an infant with MSUD will show marked increases in the levels of leucine, isoleucine, valine, and alloisoleucine level (the branched-chain amino acids). Unlike the other classic organic acidurias (discussed later), pronounced acidosis, ketosis, hyperammonemia, or other abnormalities on routine laboratory tests may not be present. The primary biochemical abnormalities are the substantially increased levels of branched chain amino acids (leucine, isoleucine, valine, and alloisoleucine) in plasma and large quantities of the branched-chain ketoacids (2-ketoacids) in the urine. The 2-ketoacids are detectable by urinary organic acid analysis or by the 2,4-dinitrophenylhydrazine test. The characteristic odor, reminiscent of maple syrup, which appears earliest in cerumen and only later in urine, will probably be detected on a cotton-tipped swab inserted in the infant's ear.

Milder variants of MSUD can be missed by NBS (Bhattacharya et al., 2006). A newborn with the intermediate variant might not have a blood leucine level elevation, or the increase may be so mild as to be below the cutoff value. In the intermittent variant, the blood leucine concentration is normal in the newborn period, becoming elevated only in later infancy or childhood during acute metabolic episodes precipitated by febrile illness or surgery. Hydroxyproline at an increased level can be mistakenly identified as leucine in NBS. This would indicate a benign metabolic disorder known as hydroxyprolinemia. Quantitative plasma amino acid analysis will differentiate this from MSUD.

Homocystinuria

Individuals with homocystinuria are clinically normal at birth but, if untreated, may develop ectopia lentis (dislocation of the lens), thromboembolism, osteoporosis, and intellectual disability. The worldwide frequency of all forms of homocystinuria has been estimated at 1 in 344,000 but may be considerably higher (Skovby et al., 2010). The newborn blood screening marker for homocystinuria is an increased level of methionine. Homocysteine can be measured in a second-tier analysis to increase specificity (Matern et al., 2007). The diagnosis of homocystinuria may be missed if the blood methionine concentration is not sufficiently elevated to be reported by the screening program at the time the newborn

specimen is collected, but reducing the cutoff value for methionine can avoid this false-negative occurrence (Peterschmitt et al., 1999).

A high methionine level alone is not diagnostic of homocystinuria. Liver disease of a nonmetabolic nature can produce a strikingly high methionine level, as can isolated hypermethioninemia (methionine *S*-adenosyltransferase I/III deficiency), a metabolic disorder that is largely benign (Chien et al., 2015). Two additional rare disorders also produce hypermethioninemia: glycine *N*-methyltransferase deficiency associated with liver disease (Mudd et al., 2001; Luka et al., 2002) and *S*-adenosylhomocysteine hydrolase deficiency, which may result in developmental delay and hypotonia (Baric et al., 2004). Confirmation of the disorder requires quantitative amino acid analyses of plasma and urine. In the infant with homocystinuria, homocystine may be detectable in plasma and urine, methionine level is increased, and cystine level is reduced. Most strikingly, plasma total homocysteine level is markedly increased. In isolated hypermethioninemia, methionine level is markedly increased in plasma, but there is no detectable homocystine in plasma or urine, and the plasma cystine concentration is normal. Plasma total homocysteine level is also normal or slightly increased. Hypermethioninemia secondary to liver disease owing to tyrosinemia type I or to non-specific liver disease is usually accompanied by increased tyrosine level.

Urea Cycle Disorders

The three urea cycle disorders routinely screened by MS/MS analysis are citrullinemia, argininosuccinic acidemia, and arginase deficiency. All three may produce hyperammonemia in the neonate, accompanied by poor feeding, tachypnea, lethargy, and vomiting. Respiratory alkalosis is characteristic. Severe hyperammonemia in the newborn is a medical emergency and should trigger prompt consultation with a metabolic specialist or referral to the NICU at a metabolic center. Discontinuation of protein administration and the provision of intravenous fluids with high caloric content are the first steps to take. Citrullinemia and argininosuccinic acidemia require L-arginine, as well as the "scavenger drugs" sodium phenylbutyrate and sodium benzoate. In arginase deficiency, however, arginine supplementation is to be avoided. Hemodialysis is required to control the neurotoxic hyperammonemia if the blood ammonia level reaches 300 $\mu\text{mol/L}$ to prevent irreversible brain damage, coma, and death. Early identification through NBS with presymptomatic or early symptomatic therapy is critical to protecting patients with urea cycle disorders. Arginase deficiency usually presents in childhood with neurologic features such as spasticity and developmental delays in infancy and mild hyperammonemia rather than severe hyperammonemia in the neonate (Crombez and Cederbaum, 2005).

Tyrosinemia

Tyrosinemia type I is an amino acid disorder that can be diagnosed in NBS by the finding of an elevation of succinylacetone level in MS/MS analysis (Allard et al., 2004). This disorder leads to liver and renal tubular disease and can later result in hepatocellular carcinoma. It is treated with administration of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (Orfadin) (Swedish Orphan Biovitrum [sobi]) and a diet low in phenylalanine and tyrosine. Tyrosinemia types II and III may be identified by an increased level of tyrosine in NBS. Tyrosinemia type II can result in intellectual disability, painful hyperkeratoses, and keratoconjunctivitis and is treated by a low tyrosine–low phenylalanine diet. Tyrosinemia type III seems to be benign, although developmental

delay has been reported (Ellaway et al., 2001). Transient tyrosine level elevations are common in neonates.

Medium-Chain Acyl-Coenzyme A Dehydrogenase Deficiency and Other Fatty Acid Oxidation Disorders

The fatty acid oxidation disorders include those in which the long-chain fatty acids cannot traverse the mitochondrial membranes to be oxidized within the mitochondrial matrix and those in which there are defects in fatty acid oxidation per se (see Tables 27.1–27.2). In either category the problem is the inability to fully oxidize fatty acids. Fatty acid oxidation is essential to supply energy as adenosine triphosphate via the Krebs cycle and as ketones in the presence of a low supply of glucose. The disorders involving defective transport concern carnitine, whereas those with defective oxidation are named according to the enzyme that is deficient (see Tables 27.1–27.2). The major clinical consequence of these disorders is fasting intolerance resulting in hypoketotic hypoglycemia, lethargy, hyperammonemia, metabolic acidosis, hepatomegaly, and sometimes sudden death. Cardiomyopathy is an additional feature of very long chain acyl-CoA dehydrogenase deficiency (VLCADD) and long-chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD). Each fatty acid disorder is associated with a specific or almost specific acylcarnitine pattern on MS/MS analysis.

The most common fatty acid oxidation disorder is MCADD. Tragically, before NBS was available, this disorder was often diagnosed only retrospectively after a sudden unexplained death, usually when postmortem examination revealed a fatty liver. This devastating outcome and a frequency of 1:15,000 to 1:20,000, comparable with that of PKU, made MCADD the primary reason for the addition of MS/MS technology to NBS (Zytkovicz et al., 2001). The primary finding in NBS is an elevation of octanoylcarnitine level. To specify MCADD, some programs have added molecular testing of the c.985A>G medium-chain acyl-CoA dehydrogenase mutation as second-tier screening. Because this mutation occurs in as many as 90% of individuals with MCADD, this additional analysis of a newborn blood specimen substantially increases the predictive value of the octanoylcarnitine level elevation (Zytkovicz et al., 2001).

The fatty acid oxidation disorder is treated by avoidance of fasting with high-carbohydrate, low-fat feedings and, of critical importance, prompt attention to acute illnesses in which vomiting occurs (Yusupov et al., 2010). Carnitine supplementation may be beneficial. Medium-chain triglycerides (i.e., MCT oil) is given for the long-chain disorders VLCADD, LCHADD, and trifunctional protein deficiency. Any infant with a fatty acid oxidation disorder should be evaluated at a metabolic center. Most of these disorders are treatable, but screening enables early diagnosis and genetic counseling for the family even when early treatment may not be effective, such as in neonatal carnitine palmitoyltransferase II deficiency (Albers et al., 2001). Short-chain acyl-CoA dehydrogenase deficiency (SCADD) is likely benign, although before NBS it was considered to be a serious disorder (Waisbren et al., 2008).

Organic Acid Disorders

Organic acid disorders are a heterogeneous group of disorders with a combined frequency of approximately 1 in 50,000 (Zytkovicz et al., 2001). Many of them can be identified through MS/MS screening (see Tables 27.1–27.2). The marker for this disease group, as for the fatty acid oxidation disorders, is an abnormal acylcarnitine pattern. If a screening result suggests an organic acidemia, a metabolic specialist should be consulted immediately. The major organic acid disorders identified in NBS are propionic acidemia, the

methylmalonic acidemias, the cobalamin (vitamin B₁₂) defects, and isovaleric acidemia.

The organic acidemias can manifest themselves in the neonatal period with a life-threatening, sepsis-like picture of feeding difficulties, lethargy, vomiting, and seizures. Metabolic acidosis virtually always accompanies this presentation, and hyperammonemia is common. In this situation, protein administration should be discontinued and replaced by the administration of intravenous fluids with high caloric content and carnitine. The hyperammonemia rarely requires specific treatment since control of the organic acid metabolites will almost always result in resolution of the hyperammonemia. The long-term benefits of early diagnosis and treatment for the clinical and neurologic development of individuals affected by an organic acid disorder are under investigation (Dionisi-Vici et al., 2006).

Galactosemia

Galactosemia typically manifests itself in the neonatal period as failure to thrive, vomiting, and liver disease (Hughes et al., 2009). Death from bacterial sepsis, usually caused by *Escherichia coli*, occurs in a high percentage of untreated neonates (Levy et al., 1977). The average incidence of the disorder is 1 in 62,000 (Levy and Hammersen, 1978).

Some screening programs use a metabolite assay for total galactose (galactose and galactose 1-phosphate) to detect galactosemia, other programs screen the newborn specimen with a specific semiquantitative enzyme assay for activity of GALT, which is usually undetectable in classic galactosemia, and a few programs use both tests as a primary screen. The enzyme assay identifies only galactosemia, whereas the metabolite assay also identifies other galactose metabolic disorders, such as deficiencies of galactokinase and epimerase. Severe neonatal liver disease and portosystemic shunting caused by anomalies in the portal system can also increase the galactose level. NBS programs that use total galactose as the primary screen usually perform second-tier GALT testing in specimens with elevated galactose level. If the newborn specimen has markedly reduced or absent GALT activity, some screening programs then perform targeted molecular testing for the most frequent mutations associated with galactosemia, particularly gln188arg and asn314asp (Elsas and Lai, 1998).

Infants having increased galactose and reduced GALT activity in NBS or those with no detectable activity when only the GALT assay is performed should immediately be seen at a metabolic center. This is particularly important in galactosemia since neonatal sepsis with meningitis, almost always due to *E. coli*, is a major threat to the galactosemic infant. If the infant is breastfeeding or receiving a regular lactose-containing formula, urine should immediately be tested for reducing substance, and blood should be tested for red blood cell GALT activity and galactose 1-phosphate. Infants with a strongly positive urine-reducing substance finding (3+ or 4+) should also have tests for liver function, including prothrombin time and partial thromboplastin time for coagulopathy, and glucose level for evaluation of hypoglycemia, especially if they are showing clinical signs of galactosemia, such as jaundice, hepatomegaly, poor feeding, and/or lethargy. Breastfeeding or lactose-containing formula feeding should be discontinued, and appropriate intravenous fluids with glucose should be given as needed. If the urine test is negative for reducing substance, the NBS result is most likely to be false-positive or indicative of a benign GALT variant (e.g., Duarte variant). Nevertheless, urine-reducing substance may be absent in infants with clinically significant variants of galactosemia. Consequently, follow-up testing should be performed

for all newborns with an initial positive galactosemia screening result.

Markedly increased galactose and normal GALT activity in NBS suggest the possibility of galactokinase deficiency. This disorder produces early-onset cataracts, which are prevented by removal of lactose from the diet. Moderately increased galactose with normal or somewhat reduced GALT activity could indicate uridine diphosphate (UDP)-galactose 4-epimerase deficiency, a largely benign disorder.

Biotinidase Deficiency

Biotin recycling is necessary for the maintenance of sufficient intracellular biotin to activate carboxylase enzymes. Biotinidase is a key enzyme in biotin recycling. Lack of biotinidase activity results in reduced carboxylase activities and an organic acid disorder known as *multiple carboxylase deficiency* (Wolf and Heard, 1991). The clinical features of the disorder are developmental delay, seizures, hearing loss, alopecia, and dermatitis. The developmental delay and seizures usually manifest themselves at 3–4 months of age. Death during infancy has also been reported.

Initiation of biotin therapy in early infancy, when the disorder is presymptomatic, seems to prevent all the features of biotinidase deficiency. For this reason, a screening test has been developed and added to NBS in a number of NBS programs throughout the world (Hart et al., 1992). The frequency of newborns identified in these programs has a wide range, from 1 in 30,000 to 1 in 235,000. The average frequency seems to be approximately 1 in 60,000 (Wolf, 2012). With presymptomatic biotin treatment, virtually all identified infants have remained normal.

Lysosomal Storage Disorders

Lysosomes are organelles required for cellular turnover and contain more than 50 acid hydrolases that catabolize macromolecules. Deficiency of the individual enzyme or a combination of enzymes and transporters can result in accumulation of the substrate and progressive cellular and organ dysfunction. The disease phenotype is a consequence of the type of substrate and its sites of turnover, and severity generally correlates with the amount of residual enzyme activity. The incidence of these disorders as a group is estimated to be 1 in 7700 to 1 in 10,000 births. Direct assay of lysosomal enzymatic activity in dried blood spots by MS/MS or fluorometry techniques is currently feasible for several lysosomal storage disorders (LSDs): Fabry disease, Gaucher disease, Krabbe disease, mucopolysaccharidosis type I (MPS I), mucopolysaccharidosis type II, Niemann–Pick A/B disease, and Pompe disease (Gelb et al., 2015). Pompe disease and MPS I are the two currently included in the RUSP.

Pompe disease, also known as *glycogen storage disorder II*, is characterized by accumulation of lysosomal glycogen, predominantly in muscles, resulting from the decreased activity of lysosomal acid α -glucosidase (GAA) due to pathogenic variations in the corresponding *GAA* gene (Leslie and Tinkle, 2013). Pompe disease exhibits a broad spectrum in regard to age of onset, cardiac involvement, and progression of skeletal muscle dysfunction. The severe infantile form manifests itself within the first few months of life and is characterized by severe progressive muscle weakness. Cardiomyopathy is present in the classic form, and without treatment death occurs within the first year of life. Late-onset Pompe disease manifests itself clinically after 1 year of age, often not until adolescence or adulthood, with a slowly progressive myopathy and minimal cardiac involvement. In general, lower GAA levels are associated with earlier onset and greater severity of the disease, although the correlation is not absolute, and diversity among

individuals with identical GAA genotypes has also been observed, suggesting the effect of other modifying factors (Kroos et al., 2012). In addition to supportive care and nonspecific treatment, enzyme replacement therapy (ERT) is available and should be started as soon as the diagnosis is established. Clinical trials have shown that infants in whom ERT was initiated before the age of 6 months, and before the need for ventilatory assistance, showed improved survival and ventilator-independent survival as compared with untreated historical controls. The overall incidence of Pompe disease is 1 in 28,000, with 28% being the infantile forms. NBS offers the opportunity to detect the infantile forms early (22 days vs 3.6 months by clinical ascertainment) and thus justifies its inclusion in the RUSP. Decreased GAA activity in the screening blood spot should prompt molecular analysis for confirmation. Homozygosity for a “pseudodeficiency” allele c.(1726G>A; 2065G>A) is associated with low GAA activity similar to that seen in patients with Pompe disease but does not cause disease. This genotype, seen in approximately 4% of individuals in the Asian population, will result in false-positive screens in the first-tier enzymatic assays.

MPS I is a progressive multisystem disorder with features ranging over a continuum of severity. It is caused by deficiency of the lysosomal enzyme α -L-iduronidase (IDUA) (encoded by the *IDUA* gene), which leads to an accumulation of glycosaminoglycans (or mucopolysaccharides) within lysosomes of the affected cells (Beck et al., 2014). MPS I is broadly categorized into Hurler syndrome (MPS I H; severe, incidence 1 in 100,000), Hurler–Scheie syndrome (MPS I H/S; attenuated; incidence 1 in 500,000), and Scheie syndrome (MPS I S). Newborns typically appear normal at birth. The severe form manifests itself within the first year of life, and the early findings are quite nonspecific (umbilical hernia, recurrent upper respiratory tract infections). Subsequently, coarsening of the facial features and gibbus deformity of the lower spine may be observed. The severe form is characterized by progressive skeletal dysplasia (dysostosis multiplex) involving all bones, decreased linear growth, and progressive and profound intellectual disability. Corneal clouding and hearing loss are common. Death, typically caused by cardiorespiratory failure, usually occurs within the first 10 years of life. The clinical onset in the attenuated forms is usually between 3–10 years of age. The severity and rate of disease progression span a spectrum, ranging from death in the teens or 20s to a normal life span complicated by disability from progressive joint manifestations and cardiorespiratory disease. Hearing loss and cardiac valvular disease are common. Neurologic and psychomotor involvement are limited in the attenuated forms. Hematopoietic stem cell transplantation (HSCT), considered the standard of care for severe MPS I, increases survival (<5% vs 65% at 10 years) and reduces facial coarseness, increases growth, improves cardiac function, and relieves hepatosplenomegaly. However, it has limited effects on skeletal and valvular manifestations or corneal clouding. It delays cognitive decline, but its impact on other neurologic complications is uncertain. Maximum benefit is achieved if it is performed before 2 years of age. ERT, available for treatment of the non-CNS manifestations of MPS I in individuals with attenuated disease, increases joint mobility, growth, and visual acuity, relieves hepatomegaly, and reduces pain. The outcomes of both HSCT and ERT are significantly impacted by disease burden at the time of initiation of treatment. Decreased IDUA activity as measured by MS/MS or fluorometry in the NBS suggests the possibility of MPS I and needs to be confirmed by molecular analysis of the *IDUA* gene and/or confirmatory biochemical testing (urinary glycosaminoglycans, IDUA activity in leukocytes or fibroblasts). Unfortunately the residual IDUA activity is not predictive of the

phenotype, and the presence of pseudodeficiency alleles renders interpretation of IDUA activity more difficult. Genotyping may help predict the expected phenotype if it reveals mutations with good genotype–phenotype correlation (Clarke, 2016).

X-Linked Adrenoleukodystrophy

X-ALD is one of the most common monogenic forms of an inherited neurodegenerative disease. It is inherited in an X-linked manner, with a prevalence of 1 in 21,000 in males and 1 in 16,800 in males and presenting females. As the name suggests, it affects the white matter and adrenal cortex. The clinical phenotype is highly variable but the neurologic manifestations are present in nearly all males by adulthood (Engelen et al., 2012). Two main neurologic presentations are seen in affected males:

1. The cerebral form manifests itself insidiously between the age of 4 years and the age of 8 years, and the initial symptoms resemble attention-deficit disorder or hyperactivity. The ongoing inflammatory brain demyelination results in progressive behavioral, cognitive, and neurologic deficits leading to a vegetative state and death within 2–5 years after onset. Among males, 35%–40% develop the childhood cerebral form of X-ALD, and an additional 20% may develop it in their lifetime.
2. Adrenomyeloneuropathy is a slowly progressive axonopathy affecting both sensory and motor spinal cord tracts manifesting itself as paraparesis, sphincter disturbances, and sexual dysfunction; all symptoms are progressive over decades. The penetrance for this form is 100% in males who escape the cerebral form initially and 65% in females.

X-ALD may present as a primary adrenocortical insufficiency without evidence of neurologic abnormality in about 10% of males, and neurologic involvement occurs subsequently. Overall, adrenal function is abnormal in 90% of neurologically symptomatic boys and in 70% of men with adrenomyeloneuropathy.

HSCT has been shown to arrest the inflammation in the early stages and thus provide an efficient treatment for the inflammatory form of X-ALD. However, it is recommended only for individuals with evidence of brain involvement by magnetic resonance imaging (MRI) but minimal neuropsychological findings and normal clinical neurologic examination findings, as HSCT can accelerate neurologic decline and is likely to be unsuccessful if it is performed after cerebral demyelination has started. Detection of X-ALD by NBS allows periodic reevaluation of adrenocortical function and MRI for detection of males with early cerebral disease, thereby providing an ideal window of opportunity for HCST to treat the cerebral form. C26:0 lysophosphatidylcholine (C26:0 LPC) measured by HPLC–MS/MS in the dried blood spot is the primary biomarker used to screen individuals for X-ALD (Matern et al., 2013). Individuals with a positive screen require plasma very long chain fatty acid (VLCFA) analysis and sequencing of the *ABCD1* gene to confirm the diagnosis. However the phenotype cannot be predicted by VLCFA plasma concentration or by the nature of the *ABCD1* pathogenic variant as the same pathogenic variant can be associated with each of the known phenotypes. Increased concentrations of C26:0 LPC in the screening specimen will also be noted in other peroxisomal disorders, such as Zellweger spectrum disorders, peroxisomal acyl-CoA oxidase 1 deficiency, and D-bifunctional enzyme deficiency.

Endocrine Disorders

Congenital Hypothyroidism

CH is the most common disorder identified by routine NBS. It is found in 1 in 3000 to 1 in 5000 screened infants (Dussault,

1993). The major clinical features of untreated CH are growth retardation and delayed cognitive development leading to mental deficiency. If treatment with pharmacologic doses of T_4 is initiated early, growth and mental development are normal.

Two screening approaches are used (Pass and Neto, 2009). One method is primary screening for low T_4 levels with secondary screening for high TSH levels. The second method is primary screening for high TSH levels. Either procedure identifies CH. Nevertheless, affected infants can be missed with either approach. This situation may be due to a lack of the identifying marker abnormality at the time of specimen collection. Specifically, the T_4 level during the first 24 hours of life in an affected newborn might not yet be sufficiently decreased for identification because of persistence of maternally transmitted T_4 . Moreover, in the premature newborn with CH, it might take 2 weeks or more for a TSH level elevation to develop (Larson et al., 2003).

The reported false-positive rates of screening for CH range from approximately 0.05% to as high as 4% (Pass and Neto, 2009). Newborns with false-positive results have transiently low T_4 or elevated TSH levels. Many of those with low T_4 levels are premature neonates with a normal TSH concentration or infants with perinatal stress and elevated TSH levels. To avoid missing CH, screening programs require a second blood specimen from each of these babies. In addition to false-positive results, a low T_4 level with a normal TSH value can result from benign T_4 -binding globulin deficiency (Dussault, 1993; Mandel et al., 1993) or hypothyroidism secondary to pituitary deficiency.

Newborns with a positive screening test result should not be labeled as having CH until diagnostic testing confirms the disorder. This is especially true if the TSH concentration reported by the screening program is normal. If CH is confirmed, however, administration of T_4 should be started without delay to prevent irreversible brain damage.

Congenital Adrenal Hyperplasia

CAH caused by steroid 21-hydroxylase deficiency occurs in 1 in 16,000 to 1 in 20,000 births (White, 2009). Infants with the salt-losing form of CAH can rapidly become hyperkalemic and die precipitously, often without a specific diagnosis. The clinical diagnosis may be suspected in the newborn girl because of ambiguous genitalia. However, the diagnosis is usually not initially suspected in boys or in girls with atypical forms of CAH in which ambiguous genitalia may not occur. Moreover newborn girls with ambiguous genitalia might not be recognized as having CAH if the ambiguity is not obvious, or they could be misassigned as boys if the ambiguity is advanced. Because accurate sex assignment and initiation of hormone therapy as soon as possible are critical to a favorable prognosis in CAH, NBS is important for early diagnosis and prompt therapy with pharmacologic doses of hydrocortisone. Consequently, testing for CAH has been incorporated into routine NBS in most programs.

Screening is based on identifying elevated levels of 17-OHP, the preferred substrate for 21-hydroxylase, and is usually measured with an immunoassay. Unfortunately, compared with other neonatal screening assays, the specificity of the CAH assay is low, and false-positive results in NBS for CAH are relatively common, with the rate often as high as 0.5%. The finding may be due to a truly increased 17-OHP level, as in perinatal stress and early specimen collection (within the first 24 hours of life), or may be due to cross-reacting steroids, such as in prematurity and low birth weight (al Saedi et al., 1996). Cross-reacting steroids are produced by residual fetal adrenal cortex or result from decreased metabolic clearance by an immature liver.

A decidedly increased level of 17-OHP suggests CAH, and the infant should be referred to a pediatric endocrinologist for management. A second blood specimen is usually requested from infants found to have a slightly to moderately increased 17-OHP level. If the infant shows signs of illness or has ambiguous genitalia, serum electrolyte levels should be measured. If these results indicate hyponatremia and hyperkalemia, the infant should be hospitalized without delay, and the electrolyte imbalance should be corrected immediately. Pediatric endocrinology consultation should also be sought. It may be possible to increase the positive predictive value by second-tier screening using DNA-based methods or liquid chromatography followed by MS/MS, but currently these methods are not widely used by NBS programs.

Sickle Cell Disease

In most NBS programs in the United States, the blood specimen is routinely tested for hemoglobin abnormalities. The major goal of this testing is to identify newborns with sickle cell disease so that they can be given penicillin prophylaxis to prevent pneumococcal septicemia. Additional benefits of early detection are early referral to a comprehensive sickle cell program and early education and genetic counseling for parents (Smith and Kinney, 1993). Unfortunately, the long-term complications are not yet preventable.

Sickle cell screening is usually performed by separation of variant and abnormal blood hemoglobins eluted from the Guthrie specimen by electrophoresis or HPLC. This procedure identifies sickle cell disease, sickle cell trait, and several other hemoglobin abnormalities. Other than sickle cell disease, most of these abnormalities are benign. It is especially important to differentiate the common and benign sickle cell trait from the much rarer sickle cell disease (homozygosity for hemoglobin S). For example, sickle cell disease affects approximately 1 in 600 African-American individuals, whereas sickle cell trait (carrier status for hemoglobin S) is present in 1 in 12. Infants with sickle cell trait do not have complications and should not be stigmatized as having sickle cell disease.

When sickle cell disease is confirmed, penicillin prophylaxis should be initiated as soon as possible, and the infant should be referred to a sickle cell disease center or hematologist. The combination of screening and careful follow-up has been highly effective in prevention of pneumococcal sepsis in infants with sickle cell disease.

Cystic Fibrosis

The frequency (1 in 2000 to 1 in 3000) and severity of CF explain its inclusion in routine NBS. As with sickle cell disease, therapy that can prevent the most serious complications of CF is not yet available. However, early and usually presymptomatic diagnosis through screening leads to early nutritional therapy, pancreatic enzyme replacement, and antibiotic prophylaxis for pulmonary infection. Data suggest that children with CF who are identified by NBS have better growth, prevention of early vitamin deficiency, and some advantage in terms of pulmonary status later in life (Farrell et al., 2001; McKay and Wilcken, 2008; Southern et al., 2009). Other benefits of NBS are identifying the parents' genetic potential for producing additional children with CF and, through presymptomatic identification, allowing the family to avoid months or years of delay in making the correct diagnosis for a child with chronic respiratory problems or poor growth (Farrell and Mischler, 1992).

The analyte marker in NBS for CF is increased immunoreactive trypsinogen (IRT) level. Transient increases in IRT level are common in healthy newborns as a result of perinatal stress or for unknown reasons. Consequently, the rate of false-positive results in CF

screening using only IRT is relatively high. To reduce this rate, screening programs have adopted a second-tier DNA analysis for a panel of CF mutations when the specimen has increased IRT level (Ferec et al., 1995). Despite this two-tiered approach to screening, a substantial number of infants who do not have CF must undergo a sweat test or complete DNA sequencing of the CF gene before the diagnosis can be ruled out.

Severe Combined Immunodeficiency

SCID includes more than 15 genetic disorders characterized by the absence of both humoral and cellular immunity and is estimated to occur in 1 in 50,000 to 1 in 100,000 births. Approximately 50% of cases are due to mutations in the *IL2RG* gene, localized on the X chromosome. Disease presentation differs, but as protection from maternal antibodies wanes during the first few months after birth, infants with SCID will usually develop infections due to both common and opportunistic pathogens. Treatment and prevention of infections can prolong life but are not curative. Early HSCT before the onset of severe infections offers the best chance of cure and has been made feasible by NBS.

As SCID is characterized by absent or extremely low production of antigenically naïve T cells from the thymus, low concentration of TRECs in the NBS specimen (marker of newly formed, thymic emigrant T cells) with a valid result for the internal control (e.g., ribonuclease P) is used to screen newborns for SCID (Comeau et al., 2010). A high-risk positive SCID NBS result prompts further diagnostic testing such as flow cytometry to measure specific T-cell markers and specialized immune function tests before the diagnosis is established or excluded. The most low-risk positive SCID NBS results are from neonates in the NICU and, depending on the testing laboratory's algorithms, may require only repeated screening. Non-SCID lymphopenias and infants who have had a thymectomy (most often during cardiac surgery) can show low TREC values.

Hearing Loss

Hearing loss is the most common birth defect, with 1 in 500 newborns having confirmed hearing loss. Infants with hearing loss not identified before 6 months of age have delays in speech and language development, while intervention before 6 months of age allows an infant with impaired hearing to develop normal speech and language. This rationale prompted the National Institutes of Health to recommend screening for congenital hearing loss for all newborns in 1993. Typically automatic auditory brainstem response or otoacoustic emissions testing is performed to detect hearing loss in the neonate. To maximize the benefits, the hearing screen should be performed before 1 month of age, preferably before hospital discharge; infants who screen positive should have a diagnostic audiologic evaluation before 3 months of age, and all infants identified with hearing loss should receive appropriate early intervention services before 6 months of age (medical, audiologic, and early intervention). Approximately 1.6 % of all newborns do not pass the hearing screen and are referred for an audiologic evaluation, and among those 10.3% are confirmed as having hearing loss. Enrollment in early intervention services among children diagnosed with hearing loss is estimated to be 61.7%. For a more detailed discussion, readers are referred to Chapter 109.

Critical Congenital Heart Disease

Congenital heart disease (CHD) is the most common cause of death in the first year of life, accounting for 3% of all infant deaths.

CHD affects about 7 in 1000 to 9 in 1000 live births; a fourth of these can be classified as CCHD, a term that encompasses the heart defects that cause severe and life-threatening symptoms and require intervention within the first year of life ([Centers for Disease Control and Prevention, 2012](#)). Currently pulse oximetry, in conjunction with a clinical examination, is the recommended screening approach and will usually identify CHD that results in hypoxemia. This group accounts for approximately 17%–31% of CHD cases and includes hypoplastic left-sided heart syndrome (HLHS), pulmonary atresia with intact septum, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus. Each condition has palliative and surgical options, with a spectrum of standard interventions for each. Overall, the 5-year survival rates after intervention range from 65% to 97%, with five of the seven conditions having 5-year survival rates greater than 85%. The two conditions with the lowest long-term survival rates are pulmonary atresia with intact septum and HLHS. The sensitivity of screening for CCHD is 30.8%, 47%, and 77% by pulse oximetry, clinical examination alone, and both, respectively. For a more detailed discussion, readers are referred to Chapter 55.

Specific Issues in Newborn Screening

Criteria for Newborn Screening

Under the auspices of the World Health Organization, [Wilson and Jungner \(1968\)](#) published a set of criteria for screening for conditions that have generally been accepted as required for population screening. The ten criteria state that (1) the condition be an important health problem, (2) there must be accepted treatment, (3) facilities for diagnosis and treatment must be available, (4) there must be a recognizable latent or early symptomatic stage, (5) there should be a suitable test, (6) the test should be acceptable to the population, (7) the natural history of the condition should be understood, (8) there should be a policy prescribing whom to

treat, (9) the cost of case finding should be economically balanced in relation to medical care as whole, and (10) case finding should be a continuing process.

These criteria were developed at a time when NBS was in its beginning stages and with screening for adult disorders in mind. For example, regarding the first criterion, Wilson and Jungner recognized that the term *important* is relative; whereas diabetes was prevalent and treatment might not influence outcome, PKU was rare, but it warranted screening because of the serious consequences that would be prevented by early diagnosis and treatment.

There is a question as to the current relevance of the Wilson–Jungner criteria for NBS. Ideally, all the criteria should be applied to NBS. However, advances in technology have caused this application to be questioned ([Green and Pollitt, 1999](#); [Levy, 1999](#)). As an example, screening using MS/MS allows detection of serious disorders for which there may not be acceptable or agreed on therapy or for which the natural history is largely unknown, challenging the criterion that any disorder included in screening should have acceptable treatment. How is this dilemma resolved? The answer is not yet available. It is hoped that the experience and findings from expanded NBS will be used to develop a new set of criteria that will apply to NBS. These criteria will likely retain the essence of the Wilson–Jungner compilation but with important modifications that could be applied to any new screening venture.

False-positive Results

The majority of positive results in NBS, particularly when the result is only mildly or moderately abnormal, are not due to a disorder. Unfortunately, because screening is primarily based on a quantitative measure, false-positive results must be addressed. Metabolite concentrations differ among individuals, and the distribution curves of the markers from affected and unaffected populations are expected to be different ([Fig. 27.2](#)). In screening, a value that separates the two distribution curves is established as a cutoff.

• **Fig. 27.2** Distribution of quantitative markers measured in screening. For most conditions the distribution in the unaffected or normal population overlaps that in the affected individuals. The number of false-positives (FP), false negatives (FN), true positives (TP), and true negatives (TN) depends on the established cutoff.

The cutoff values of the quantitative biomarkers are established by the individual screening laboratories, and they can differ among the different laboratories because of variations in the testing technology. In general, the cutoff value should be set such that it is different (greater than or less than, depending on the condition) than the 99th percentile of the concentration in normal neonates and the 5th percentile of the concentration in affected neonates (Rinaldo et al., 2006). However, for disorders that are extremely rare, the population of affected neonates may be so small that establishing an appropriate cutoff becomes a challenge. In such cases, the laboratory may empirically set a cutoff at three to four standard deviations from the population mean and adjust the values with experience to minimize the false-positives without compromising the sensitivity. Specimens in which the concentration crosses the established cutoff are considered screen positive. For disorders characterized by an increased metabolite concentration, the concentrations in most unaffected infants are below the cutoff value, but in a small proportion the metabolite concentration crosses this threshold. These latter screening results are considered false-positives. Because of some degree of overlap in the distribution curves of the affected and unaffected populations, these false-positives cannot be entirely eliminated without compromising the sensitivity of screening. Furthermore, other physiologic factors, such as immaturity of metabolic enzymes, stress, and therapeutic interventions, can skew the concentrations of certain metabolites and lead to false-positive screening results. Currently, the indicators measured by immunoassays (e.g., 17-OHP in CAH and T_4 in CH) or enzymatic activity (low GALT activity in galactosemia) are associated with the highest false-positive rates.

The false-positive results are more common in preterm and low birth weight infants than in term infants. For example, up to 85% of preterm infants have transiently low T_4 levels (Paul et al., 1998). Transient increases in 17-OHP level are another common abnormality in infants who are preterm or have low birth weights or have experienced perinatal stress (Pang and Shook, 1997). In addition, transient tyrosinemia is commonly observed in preterm and low birth weight infants, although it can also occur in term infants (Levy et al., 1969).

Artifacts produced in the collection or transport of the Guthrie specimen account for some false-positive results. As mentioned in the discussion of the specimen collection procedure, obtaining the specimen from a central line can result in mixing with the amino acids in the TPN solution and consequently a false increase of the levels of amino acids in the specimen. Even with correct specimen collection, TPN can produce a transient amino acid level increase. Contamination with milk (or any drink containing milk) can result in a false elevation in galactose level and the mistaken suspicion of galactosemia. Prolonged exposure to heat can reduce the activity of GALT in the specimen and produce a false impression of galactosemia when the enzyme assay is used to screen an individual for this disorder. This error is common during the summer, especially when the specimen remains in a mailbox for some time. Some factors known to be associated with false-positives are shown in Table 27.3 (Sahai and Marsden, 2009).

With the substitution of MS/MS for the traditional bacterial or specific assays, such as those for PKU and MSUD, the number of false-positive results is distinctly lower. For PKU screening, the false-positive rate is reported at 0.05%, compared with 0.23% for earlier methods (Levy, 1998). In addition, with MS/MS the multiplexed approach allows a profile of analytes rather than a single analyte level (e.g., phenylalanine/tyrosine ratio vs only a

phenylalanine level for PKU identification), further increasing the specificity of screening (Chace et al., 1998; Schulze et al., 1999). Therefore the average positive predictive value for primary markers analyzed by MS/MS, previously reported to be 8%–10% (Schulze et al., 2003; Wilken et al., 2003), can be increased substantially if the marker is evaluated in context with other metabolites that are screened or when a tiered approach is applied (Frazier et al., 2006; Sahai et al., 2007; Marquardt et al., 2012).

Second-tier assays, such as molecular assays for CF or secondary immunoassays for hypothyroidism, are commonly performed to reduce the false-positive rates for primary markers analyzed by immunoassays or enzymatic assays. Nevertheless, false-positive results cannot be entirely eliminated; therefore it is important to reassure the parents that not every abnormal result of NBS inevitably implies a disorder and that transient or nonspecific abnormalities are common. Although all infants with an abnormal screening result must undergo repeated testing, the families should be informed that an initial positive result might have no medical implications. This approach can alleviate excessive anxiety and prevent unnecessary diagnostic procedures and treatment.

Increased Detection by Screening

For certain disorders screened by MS/MS, many more infants are identified than the numbers previously expected solely on the basis of clinical identification. The greatest increases are in the fatty acid oxidation disorders, including SCADD, MCADD, VLCADD, and carnitine uptake defect and in three organic acid disorders (glutaric acidemia type I, 3-methylcrotonyl-CoA carboxylase deficiency, and 3-ketothiolase deficiency; Wilken et al., 2003).

Although individuals who are symptomatic but with no diagnosis could account for some of the clinically identified cases, it is likely that the greater part of the excess represents infants with benign or milder forms of the disorders who did not come to clinical attention. Notably, Spiekerkoetter et al. (2003) identified a frequent mutation in asymptomatic patients with VLCADD detected by NBS, and Ensenauer et al. (2004) found a common, mild, and perhaps asymptomatic mutation in patients with isovaleric acidemia identified by screening. More recently, Spiekerkoetter et al. (2010) have demonstrated that most infants assumed from NBS to have VLCADD are either false-positive or have an enzymatically very mild form of the disorder that is most likely to be benign.

Missed Cases

A few infants with CH, PKU, intermittent MSUD, glutaric acidemia type 1, tyrosinemia type I, and other screened disorders have been missed by NBS. Laboratory or program errors were reported as the most common cause of these missed cases (Holtzman et al., 1974). In some instances, a specimen was never collected, such as when infants were transferred to another hospital. However, in screening for a multitude of disorders, each with its own biomarker that varies with time and physiologic states, an occasional affected neonate may have normal biomarker concentrations in the newborn specimen simply because the timing of collection was not ideal for that particular condition. Therefore physicians must exercise clinical judgment and not fall into the trap of excluding a diagnosis because an infant has presumably been screened. Specific testing should be performed in any patient with symptoms that suggest the presence of a disorder, regardless of the assumed or actual NBS result.

The Future

Many factors are impinging on NBS, including rapidly advancing technology, new and increasingly available therapeutic approaches to previously untreatable disorders, and advocacy by family support groups and influential citizens or legislators who are heavily invested in individual disorders that may or may not be ready for inclusion in screening tests. To address these pressures, the Advisory Committee on Heritable Disorders in Newborns and Children meets regularly to study newly proposed NBS tests (and those currently recommended) to judge their suitability for inclusion in the screening panels. This process has resulted in the addition of SCID, Pompe disease, MPS I, and X-ALD to the RUSP. Other candidate conditions being considered include fragile X syndrome and Smith–Lemli–Opitz syndrome. These disorders will be judged on the basis of frequency, severity, availability of preemptive therapies, and the cost and robustness of the screening test itself. Some disorders have been included in isolated state panels on the basis of the political influences mentioned earlier.

The most controversial and potentially the most far-reaching possible addition to NBS is genetic screening. This possibility is the result of next-generation sequencing, a dramatic technological advance in allowing the sequencing of nucleotides in the genome as well as an equally dramatic reduction of the cost for this sequencing (Landau et al., 2014). Genetic screening could be whole-exome sequencing, which could include all of the exons in selected genes or even in the entire genome or whole-genome sequencing, which would include exons and introns of selected genes or the entire genome. Any of these approaches could possibly be applied to the DNA in the screening specimen and result in an enormous expansion of NBS, potentially identifying mutations for many genetic disorders, nonmetabolic as well as metabolic, not currently covered by NBS. It could be additive to current screening or could replace to a degree as well as add to current NBS (Levy, 2014; Howard et al., 2015).

Nevertheless, the challenges of genetic screening would be formidable. The most formidable initial difficulty would be interpreting the clinical implications of the data. An enormous amount of bioinformatics would be required. Even with a huge degree of bioinformatics, the clinical significance of most of the sequence changes would be unknown (variation of unknown significance). The time required to process and interpret the data would increase the turnaround time of NBS from the current 2–4 days, thus potentially delaying the initiation of treatment for disorders in which very early treatment may be critical. Assuming these and other difficulties would be resolved, there would remain the problem of genetic screening based on the recognition of mutations, greatly increasing the number of infants with benign variations of disorders who would receive otherwise unnecessary medical tests and perhaps unnecessary treatments. These challenges do not even address the medical genetic services needed that would far exceed the current availability, the greatly increased need for confirmatory tests, and the huge amount of uncertainty and anxiety in families that genetic screening would generate.

A much more limited genetic screening, however, could be envisioned. Some degree of specified NGS of a few key genes in which the mutations and their implications are well known could be added to current NBS with a two-stage NBS reporting procedure in which the current screening results are reported promptly and the genetic screening results reported later. The disorders targeted would be those in which early treatment might not be critical or

even available but in which diagnosis would be important for defining the origin of illness and/or for family considerations. This screening would require informed consent and would have to be very carefully constructed. To examine these questions, the National Institute of Child Health and Human Development and the National Human Genome Research Institute have funded four major 5-year pilot projects to examine the potential of genetic NBS. These projects include the technical feasibility of applying genomic sequencing to the NBS specimen, to examine the medical effectiveness of sequencing in a neonatal setting, and to address the ethical, legal, and societal implications of sequencing in NBS (<https://www.nih.gov/news-events/news-releases/nih-program-explores-use-genomic-sequencing-newborn-healthcare>).

Finally, there is the issue of retention of blood spots for future study. Despite multiple safeguards to protect the identity and anonymity of individuals, parents and civil libertarians are concerned that retention of these blood spots poses a threat to the privacy of individuals and that the specimens should be destroyed. If this view prevails, a resource of great value in the development of new and more effective tests, and one that is increasingly recognized as the avatar of personalized medicine, will be lost.

Neonatal Transport

LILA O'MAHONY AND GEORGE A. WOODWARD

KEY POINTS

- Regionalization of neonatal critical care improves outcomes.
- Highly effective neonatal transport systems feature centralized communications, experienced medical oversight, and skilled teams trained to care for sick neonates.
- Appropriate transport care depends on the competency of the transport teams.
- The care delivered to the patient should not decrease in sophistication at any time during the transport process.
- The referring provider is responsible for ensuring the adequacy of the chosen mode of transport.

Controversies

- Optimal transport team composition and configuration
- With proliferation of midlevel neonatal intensive care units, determining or anticipating which patients require transfer to higher levels of care and when
- Optimal method to achieve and monitor neonatal therapeutic hypothermia during transport

Regionalization of medical care enhances the ability to centralize resources and has improved patient outcomes. For optimal coordinated care, however, an adequate medical transport infrastructure needs to be developed and continually refined to enable delivery of patients to regional centers and for specialized care to be available for and delivered to patients in need. For centers that provide basic or specialized service, there will be times when subspecialty care is required, and for those who deliver subspecialty care, there may be times when transfer is indicated for reasons such as capacity or extraordinary care (i.e., extracorporeal membrane oxygenation [ECMO]). For hospitals that do not have birthing centers but to which neonates are brought for care, transfer may be indicated, and potential morbidity and mortality of these patients depend on high-quality and efficient neonatal transport. Although transfers to neonatal centers in the 1960s and early 1970s often occurred in an ad hoc manner, such as in a police car or a general ambulance, transfer programs today offer a more sophisticated level of care. Many transport services and centers have grown around individual center needs, without clear attention to coordination and regionalization of

services. Competitive systems, often located in similar areas or vying for similar patient populations, have resulted in the duplication of services at the ground and air levels and at times increased risk and cost to patients and providers as part of the efforts to maintain or increase patient volume and revenue. Furthermore, national and international standards of care in neonatal and pediatric transport medicine are evolving.

When considering transport of neonatal patients, several situations can occur: *intrafacility* for specialty services within a particular institution and *interfacility*, often between lower and higher levels of service capability, as well as between relatively equivalent levels of service because of capacity or other issues. Transported patients may be of high acuity, relatively stable, or in various stages of convalescent care. Each type of transport requires anticipatory planning, skilled, qualified, and certified transport personnel, adequate modalities (e.g., transport vehicles), and strong communication and relationships between referring and receiving providers. As noted in the next section, transfer agreements may help minimize inefficiencies and enable rapid approval and eventual transport of patients.

This chapter will review considerations and requirements for neonatal transport; discuss issues involved in transport team operation, including equipment, personnel, mode of transport, and medical legal issues; and present general and specific topics, including quality improvement opportunities, that might be encountered in a neonatal transport system (Cornette, 2004; American Academy of Pediatrics, 2016).

Regionalization of Neonatal Care, Care in the Community, and Transfer Agreements

Historical Perspective

The concept of regionalization of neonatal care and transport developed from the formation of neonatal stations, areas within hospitals, in the 1920s and 1940s (Oppenheimer, 1996) that had additional resources to care for premature neonates. One consequence of the formation of these stations was the development of equipment and protocols to transport premature neonates from other area hospitals to those with specialty services.

In the 1960s and 1970s, as interest in neonatal care grew, so did the number of hospitals offering services for premature infants.

To help optimize the care being delivered, the March of Dimes produced *Toward Improving the Outcome of Pregnancy: Recommendation for the Regional Development of Maternal and Perinatal Health Services* in 1976 (Committee on Perinatal Health, 1976). The report stratified maternal and neonatal care into levels based on complexity, and it proposed the referral of high-risk patients to centers with sufficient personnel and resources to provide care. The goal was to create standard definitions so that comparisons of health outcomes, resource utilization, and costs among regional institutions could be made. High-risk maternity patients would be able to actively participate in selecting a delivery service, and businesses would be able to select appropriate healthcare resources for their employees. The subsequent March of Dimes publication in 1993 *Toward Improving the Outcome of Pregnancy: The 90s and Beyond* reiterated the importance of regionalized care and further delineated care levels (Committee on Perinatal Health, 1993). The concepts of regional care were adopted and incorporated into the Guidelines for Perinatal Care (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al., 2007). Whereas the original driving forces for regionalization in the 1970s were the shortage of centralized trained personnel to care for low birth weight (LBW) neonates and the economic expense to maintain these skills, during the late 1980s and 1990s, technology and clinical expertise disseminated outside the regional tertiary centers, resulting in proliferation of the number of intermediate-care neonatal intensive care units (NICUs). This proliferation has blurred many of the original distinctions between various care systems. Whether driven by third-party payers or other factors, with various interpretations and applications of what “regional care” means, the results have been the creation of a variety of care options (Lainwala et al., 2007) but without necessarily improved or optimal outcomes for all patients. For example, Kastenber et al. (2015) found that very low birth weight (VLBW) neonates with necrotizing enterocolitis had significantly increased mortality when cared for in low-volume mid-level NICUs compared with higher-volume units and those with higher acuity status. While there is limited robust evidence that demonstrates a clear causal relationship between improved outcomes and regionalized systems of neonatal care (Rashidian et al., 2014), understanding the impact of deregionalized systems on quality of care and patient outcomes will help inform which neonates require transfer to regional, high-volume, high-acuity centers and how to optimize use of the neonatal transport system to meet these needs.

Care in the Community and Back Transport

Regionalization of care, space limitations, and longitudinal care coordination contribute to a current system in which neonates are being both transported to higher levels of care for acute and/or critical needs and also transported back (“back transport”) to appropriate centers, perhaps closer to home, once their critical condition has resolved or stabilized (Lynch et al., 1988; Donovan and Schmitt, 1991; Attar et al., 2005). Regionalization guidelines should support the return to community facilities for patients who no longer need the highest level of care. Patient selection for back transport and care in another facility should match the capabilities and expertise of the community hospital (Stark and American Academy of Pediatrics Committee on Fetus and Newborn, 2004). The increasing application of telemedicine and technologies that allow real-time assessment and medical guidance may enhance not only the capacities of more remote facilities and providers during initial stabilization but also those for ongoing care of high-risk

neonates. In addition, telemedicine applications may augment the assessment and care provided by the transport team when at the patient bedside when they are able to communicate in real time with specialty providers at a receiving facility. Kim et al. (2013) conducted a prospective study to assess the impact of telemedicine in Arkansas on regionalized care and infant mortality. They found that there were fewer VLBW neonates born outside hospitals without NICUs and an overall decline in infant mortality statewide. Webb et al. (2013), in a multicenter study assessing the impact of telemedicine on neonates with suspected congenital heart disease (CHD), observed improvements in the diagnosis of CHD, fewer patient transfers, reductions in the length of stay, and use of inotropes and indomethacin. Telemedicine is a rapidly growing area in medicine, with increasing presence in NICUs, and an area of continued opportunity for development for transport.

Transfer Agreements

Although third-party payers often drive decision making, transport relationships can develop between various institutions by formalized transfer/preferred provider agreements and/or by historical and personal relationships (Attar et al., 2005). Transfer agreements can help to define the roles, understanding, and expectations between institutions and the transport service; they also help frequently to detail reimbursement issues. These agreements set the expectations for participating facilities, with the ultimate goal of the timely movement of patients from one facility to another (Woodward et al., 2007; American Academy of Pediatrics, 2016). Agreements should be reviewed by legal counsel to ensure compliance with state law (American Academy of Pediatrics, 2016).

A neonatal transport system must also determine if maternal transport is part of its purview. It is clear that preterm neonates who are born outside hospitals and require transfer to tertiary care centers or transfer between tertiary care centers have worse outcomes, which include increased mortality and morbidity such as intra-ventricular hemorrhage (Janse-Marec and Mairovitz, 2004; O'Brien et al., 2004; Jony and Baskett, 2007; O'Hara et al., 2008; Baskett and O'Connell, 2009).

Several investigators have shown that mortality is lowest for deliveries of VLBW neonates that occurred in hospitals with tertiary care NICUs (Robertson et al., 1994; Chien et al., 2001; Phibbs et al., 2007; Rautava et al., 2007). Clark (2003) supported the idea that, whenever possible, women in early preterm labor should be moved to the regional hospital rather than the neonate being transferred after birth. The study was insufficiently powered, however, to make a recommendation regarding the difference between regional and large community NICUs (Clark, 2003). In trying to discern which LBW neonate might be better cared for in tertiary regional care centers, Vieux et al. (2006) showed that there were factors associated with both increased and decreased need for neonatal intensive care. These data can help inform guideline development for transporting women in preterm labor and optimize the use of transport and local community resources to ensure timely transfer and optimal patient outcome.

Transport Communication

When one is developing and maximizing transport capabilities, a key concept is centralized communication, often in the form of a communication center. While a call from a referring provider directly to a receiving provider might seem to be the most efficient way to initiate a clinical conversation about a potential transport,

• BOX 28.1 Features of a Highly Functional Centralized Communication Center

- Centralized number with immediate access to transport system or center personnel 24/7
- Contact number advertised, easily recalled, monitored 24/7
- Single call or point of contact for referring provider to accomplish all transport needs
- Dedicated communication center personnel with transport-specific training
- Recorded calls for quality assurance and quality improvement activities

Data from Southard PA, Hedges JR, Hunter JG, Ungerleider RM. Impact of a transfer center on interhospital referrals and transfers to a tertiary care center. *Acad Emerg Med*. 2005;12:653–657.

there are more effective means of communication. Those who have transported or referred patients in systems without centralized access understand the challenges in working through operators, unit clerks, multiple providers, and often multiple services to enable a singular transport. This process is time-consuming and often frustrating for the referring provider, and the time could be better spent in direct assessment and care of the patient. When one is communicating with the transport system, there are key elements that must be considered and appreciated on both sides to initiate and complete a successful patient transfer:

1. Appreciation and recognition of the need for transfer
2. Awareness of appropriate and available transport modality and options
3. Identification of appropriate receiving facility and acceptance by receiving provider
4. Verification of regional and local bed capacity
5. Review of current medical issues
6. Determination of required transport services, including personnel
7. Dispatch of transport team and potential limitations

Centralized access through a communication center can allow all those functions to occur simultaneously, enabling more rapid transport response and appropriate involvement of all individuals required for the care of a particular patient ([American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007](#); [Woodward et al., 2007](#)) (Box 28.1).

Medical Supervision

A key requirement for any system is to have appropriately skilled and immediately available medical command physicians (MCPs) (also referred to equally as *medical control physicians*) ([American Academy of Pediatrics Committee on Fetus and Newborn, 2007](#); [Woodward et al., 2007](#); [American Academy of Pediatrics, 2016](#)). An MCP should be literate and expert in the medical area of concern, as well as up to date on transport capabilities. In most cases involving neonatal transport, this provider should be a neonatologist. There may be instances, however, when the referring or receiving physicians may request or desire additional medical expertise. For example, a cyanotic newborn with CHD may be temporarily stabilized by the referring provider and additional medical advice may be provided by the receiving MCP, as well as a partnering cardiac intensive care physician. A communication center can facilitate an initial call in which multiple providers are linked, allowing the highest level of advice to be presented and discussed among providers. These telephone calls should ideally be recorded for quality control and/or for review if verification of

TABLE 28.1 Characteristics of Mode of Transport

| Transport Modality | Distance to Receiving Facility (Miles) | Features |
|--------------------|--|---|
| Ground | 10–20+ | <ul style="list-style-type: none"> • Fewer weather restrictions • Door-to-door • Well-lit care environment • Space for family, providers • Efficient in urban, short-range transfers |
| Rotor wing | >20–100 | <ul style="list-style-type: none"> • More expeditious >50 miles, ideal efficacy 50–150 miles • Can access less accessible areas • Can potentially be door-to-door |
| Fixed wing | >100 | <ul style="list-style-type: none"> • Expeditious over long distances, ideal efficacy >150 miles • Can circumvent weather issues • Potential space for family, provider • Ability to pressurize cabin • Requires ground transport to and from airports |

information is needed and should include the transport personnel so that background information and care plans are communicated directly.

Mode of Transport

Once the transport referral has been made and discussions have been started with the MCP, the transport process begins in earnest. A decision on mode of transport is an important consideration at this juncture and is ultimately the responsibility of the referring provider, although it can be appropriately influenced by the MCP. (Table 28.1).

In addition to distance from the referring and receiving facilities, which will impact the total transport time, the decision regarding the mode of transport is influenced by several additional considerations when aiming to arrange and dispatch the most appropriate team for a given patient:

- Available mode of transport
- Staffing and medical expertise of providers involved in each mode
- Patient's current stability and potential illness progression during the projected transport time
- Capabilities of referring facility and personnel
- Urgency of need for intervention and definitive care of patient
- Geography and weather

In a study examining the decision-making factors around the mode of transport, [Quinn et al. \(2015\)](#) found that the decision to activate a helicopter versus a ground unit was made in the face of not only prolonged distance (>45–60-minute drive time) but also the presence of perceived high-risk clinical conditions, specifically neurovascular and respiratory concerns, even more so than blood pressure or heart rate.

Currently, there are guidelines but no national absolute criteria or standards to direct the choice of ground versus air transport. Each modality has its own risks and benefits. First, with both air

and ground transfer, concerns include potential physiologic stress and discomfort experienced by the neonate secondary to stimuli such as vibration and noise (Schierholz, 2010; Sittig et al., 2011; Bouchut et al., 2011; Harrison and McKechnie, 2012; Karlsson et al., 2012; Prehn et al., 2015). Therefore adjuncts to minimize the stress and discomfort, such as gel mattresses and earmuffs, should be used as much as possible. Air transport can also present specific stressful stimuli such as gravitational forces during acceleration and deceleration, temperature variations, and decreased humidity with altitude and introduces issues related to altitude physiology that can affect patients with respiratory issues or air trapping as well as air-containing equipment (e.g., endotracheal tube cuffs, laryngeal mask airways) (Woodward and Vernon, 2002; Wilson et al., 2008; Woodward et al., 2006; Schierholz, 2010). Dalton's law recognizes that ambient oxygen partial pressure decreases as altitude increases; therefore there may be a need for pressurization and augmentation with increased fraction of inspired oxygen. Boyle's law states that as altitude increases, the volume of a gas also increases, as barometric pressure is inversely related to the volume of the gas. Thus consequences of this law are potentially a serious issue for patients with an enclosed gas collection, such as a simple or developing pneumothorax or pneumatosis in suspected cases of necrotizing enterocolitis.

Secondly, weather and physical distance can make each mode of transport more or less accessible or reasonable at a given time. For instance, while ground transport may be more readily available than air transport because of fewer weather constraints and an increased number of vehicles, the overall transport time may be too long given the clinical needs of the patient.

Finally, each mode of transport has occupancy limitations associated with select vehicles, especially rotary air transport. These limitations can preclude extra passengers such as parents or family members or potentially crew members if weight and balance is an issue.

Transport Personnel, Education, and Team Composition

Awareness of the capabilities of the transport system and of the personnel involved is imperative in decisions regarding the mode of transport. Although it is ultimately the responsibility of the referring physician to identify the appropriate mode and personnel for transport, per the federal Emergency Medical Treatment and Active Labor Act (EMTALA), opportunities exist for tertiary care and referral centers to help inform the referring providers regarding optimal transport planning and use (Bolte, 1995; Woodward, 1995). In general, issues influencing transport decisions include the patient's current level of care, urgency for a different level of medical capability or equipment, current provider capabilities, stability of the patient, options available to the provider and patient, and efficiency and quality of the transport process. Ideally, these issues are key determinants of appropriate transfer; however, referring providers are often overwhelmed by the severity or acuity of the patient, and their primary desire may be to have the patient removed from their facility as quickly as possible. The providers may focus on a transfer process based solely on the speed of transport rather than the quality of care. It is imperative for the receiving and tertiary care centers to educate the referring providers regarding the importance of stabilization, initiation and quality of the primary response, transport options, and definitive care to maximize patient outcome. When examining the transfer of patients, providers should

ask a simple question: Are we trying to deliver the patient to tertiary care, or are we trying to deliver tertiary care to the patient? In most high-functioning transport and referral centers, the latter is true. The referring physician should expect to have tertiary care advice and direction delivered at the moment of the referral call and continued throughout the transport process (Woodward, 1995; American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al., 2007).

When considering the transport team composition, it is important to consider the quality of the personnel, their expertise and experience, and their ability to work in the transport environment (King et al., 2001; King and Woodward, 2002a; King et al., 2007). There are many variations of transport teams in the United States and abroad (Karlsen et al., 2011). These teams can be composed of a combination of physicians, nurse practitioners, nurses, respiratory therapists, paramedics, and other healthcare providers. Regardless of the formal educational background of an individual, there are several criteria that must be met to be optimally effective in the transport environment. First, the provider must have adequate certification, be licensed for the care he/she delivers, and be able to provide the assessments and interventions that a patient currently or potentially requires during the transport process. For example, a neonatal retrieval service must be able to manage acute and critical airways in the neonatal population, both at a referring hospital and during the transport. While transport team providers might not be credentialed to provide certain skills within their home hospital (i.e., intubation), they have been certified to provide them in the ambulance environment. In general, this must be done under the auspices of a physician's care, which may be from an accompanying physician or via online medical control (real-time medical advice during the transport process) or protocol-based care (off-line medical control). It is important to recognize that the transport time frame is somewhat limited; therefore the personnel may not need to have the longitudinal or differential diagnosis expertise of a fully trained neonatologist. However, these personnel must have the acute care assessment abilities and intervention skills of an experienced neonatal expert.

From the transport and pediatric literature, patient outcomes are improved with specialty providers. While multiple studies have examined this particular issue (Mullane et al., 2004; Belway et al., 2006; Borrows et al., 2010; Kuch et al., 2011), the most compelling is the study by Orr et al. (2009), which examined transport by variable providers within the same system. This study compared outcomes in patients whose care was delivered by specialized pediatric critical care teams with those whose care was delivered by general providers. Both teams had the same medical command oversight, equipment, and modalities. Patient outcomes were worse for those whose care was not delivered by specialty teams and was much improved for those whose care was delivered by specialty teams. While the study by Orr et al. and studies by others are compelling, a recent Cochrane review that focused specifically on neonatal specialty teams (Chang et al., 2015) concluded that in the absence of randomized controlled studies there is not good evidence to refute or support the use of neonatal specialty teams for high-risk neonates. Evidently, specialty teams and patient outcomes is an area for ongoing investigation.

In addition to training the transport personnel, MCPs should understand the opportunities and limitations of the transport services, the environment, and the risks and challenges that referring personnel can potentially encounter with situations and patients who exceed their own or their facility's management abilities. It is imperative that MCPs have clear and efficient communication,

not only with referring providers and those from different disciplines but also within the transport team.

Quality Improvement

Throughout medicine, there is an increasing focus on measuring and improving the quality of care provided across all healthcare domains and patient experiences. Transport medicine offers an opportunity for potential quality improvement activities within the inpatient arena, in the transport system, and at the referring facilities (Chen et al., 2005; Browning Carmo et al., 2008; Lim and Ratnavel, 2008; McPherson et al., 2008; Ramnarayan, 2009). While there are guidelines of care and process recommendations such as those provided through the American Academy of Pediatrics and the Commission on Accreditation of Medical Transport Services, formal national transport benchmarks or standard quality-of-care metrics are still evolving. A consensus document on behalf of the American Academy of Pediatrics Section on Transport Medicine was recently published that offers 12 core quality metrics for neonatal and pediatric transport (Schwartz et al., 2015). The proposed neonatal and pediatric transport national benchmark and quality metrics are as follows:

1. Unplanned dislodgement of therapeutic devices
2. Verification of tracheal tube placement
3. Average mobilization time of the transport team
4. First-attempt tracheal tube placement success
5. Rate of transport-related patient injuries
6. Rate of medication administration errors
7. Rate of patient medical equipment failure during transport
8. Rate of CPR performed during transport
9. Rate of serious reportable events (http://www.qualityforum.org/Topics/SRE/List_of_SREs.aspx)
10. Unintended neonatal hypothermia on arrival at destination
11. Rate of transport-related crew injury
12. Use of standardized patient care handover

The authors propose that these metrics serve as benchmarks and help guide individual program quality improvement. Details of their recommendations can be accessed at <http://www.aap-sotm.org>.

Neonatal and pediatric airway management may be one of the most important aspects of transport clinical care and historically is one of the more challenging areas for emergent and prehospital management. Examples of quality-based investigations reflect these challenges and provide information to guide improvements. Bigelow et al. (2015) retrospectively assessed first-pass intubation success for neonatal and pediatric patients across nine transport programs over a 6-month period. The overall success rate was 64%, with a range of 35%–87%, but was highest for teams that had live-patient training for initial competency and lowest for those using simulation alone. Smith et al. (2015) considered risk factors for intubation failure among neonatal and pediatric specialty teams and found higher rates of intubation failure for neonates compared with pediatric patients, especially for the smallest neonates necessitating the use of tube sizes of 2.5 mm or less. Additional risk factors for failure were the use of uncuffed tubes and the failure to use sedation and the lack of neuromuscular blockade.

Quality improvement activities in the transport domain are diverse and range from assessment of the transport process by review of recorded calls to the monitoring of intubation success and vital signs in transport to improving communication through standard handovers (Weingart et al., 2013). However, this glimpse into facility/provider medical sophistication and capability is one that is privileged and should be used to identify educational

opportunities for all providers involved rather than used as a judgmental review. Education by receiving physicians and transport teams can have a significant effect on the quality and outcome of patient care and the volume of future referrals. Ideally, once a referral call is made, a receiving physician or MCP will direct the care so that the job of the transport team is to verify that an appropriate working diagnosis has been made and adequate stabilization has been achieved. Systems that do not gather adequate information or offer appropriate advice, or in which the referring facilities do not follow that advice or choose not to perform needed interventions, can put the patient at risk by delaying potentially necessary interventions, prolonging the transport process, and delaying delivery of definitive care. The transport team that has invested several hours at a bedside stabilizing a newborn with medical or surgical issues may be spending time in a facility that is not ideal, has a limited number of skilled personnel, and has minimal backup, thus prolonging the transport process, delaying definitive care, and potentially putting that individual patient and the transport team at risk (Chen et al., 2005; Haji-Michael, 2005). Furthermore, during this prolonged stabilization time, the entire system becomes at risk because the valuable resource of specialized neonatal transport personnel is not available for another patient.

Ideally, care delivery would be the same at referral and receiving centers, and the development of practice guidelines can help in this regard. Guidelines that are evidence based, developed by regional and local experts, and disseminated to referring centers and transport teams will help standardize and promote consistent care across variable locations. It is necessary, however, to assess and reassess the quality of the guidelines and the competency of their use to ensure optimal results. Even in the best of hands, near-miss or realized adverse events may happen. It is clear that identification of those events, discussion with families (where appropriate), and root cause analysis are imperative. Several studies have examined adverse events in transported patients. Van den Berg et al. (2015) looked at adverse events over 13 years with their neonatal transport team in northern Sweden. They found that such events had differing significance (53% low risk to 11% high or extreme risk), were common, and were often related to transport logistics and equipment failure. Ligtenberg et al. (2005) noted that one-third of patients had an adverse event, and 50% of adverse events resulted from the advice of the MCP not being followed. Of that group, 70% of events were avoidable and 30% involved logistical issues. In a review of the London Neonatal Transfer Service, Lim and Ratnavel (2008) noted that 36% of their patients had one or more adverse events and that two-thirds of those were due to human error. Half of the events occurred before the team arrived at the referral center and were due to patient preparation and communication issues.

Transport Administration

As a hospital develops and optimizes a neonatal transport program, experts in transport medicine are integral to the success of the program (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al., 2007). A quality medical director and program director, often a nurse or respiratory therapist, are essential for understanding the potentially complicated and challenging environment of transport medicine. These leaders should be instrumental in identifying expectations, roles, and responsibilities for the entire transport process, including oversight of the communication center and developing and disseminating referral center expectations.

The responsibilities of the referring center when transferring patients are to:

- Stabilize and prepare the patient before transport.
- Make an appropriate decision to transfer the patient.
- Choose an appropriate transport process and destination.
- Obtain family consent for transport, including the mode and receiving facility.
- Discuss and initiate a plan for stabilization with the medical command physician.
- Communicate clearly when suggested interventions are beyond the scope of the referring center or cannot be done.
- Be present and participate in the transition of care to the transport team and the receiving service.

In turn, there are also clear expectations of the receiving center and transport team.

- Immediate availability for patient care consultation
- Able and qualified to provide clear and concise recommendations
- Quick determination if able to accept the patient for transfer
- Ensure that receiving facility staff are prepared for both patient and transport team arrival.
- Document interaction with and recommendations to the referring facility.

Most importantly, the team needs to ensure that appropriate skills and therapeutics are available and delivered throughout the process, from the referral call through definitive placement, and ensure seamless transition at each point of care. The team needs to communicate well with the patient's physicians and document their advice, interventions, and activities in a clear, concise fashion to enable appropriate patient care and provide protection for the transport service.

Transport Safety

Safety of the transport system and its providers is paramount and must be assessed and ensured before any patient is transported. Vehicles must be safe and meet the standards for air or ground transport; the personnel must be trained and skilled in the care of neonates, licensed, and competent; and the patients must be managed in the most appropriate and professional fashion. In addition, the logistics of travel must include a safe environment, including helmets and fire-retardant suits for those who fly in helicopters, three-point restraints, and appropriate ambulance seating arrangements. Providers should not put themselves at risk by being unrestrained or being in an area where unsecured debris or inappropriately placed equipment may cause harm to them or the patient. Adherence to all rules and regulations of air and ground travel is essential (Clawson, 2002; King and Woodward, 2002b; Levick, 2006; Greene, 2009; National Highway Traffic Safety Administration, 2009).

It is important to recognize that there are risks with both air and ground transport. The air transport industry saw a spike in tragic and fatal air accidents (Greene, 2009; National Transportation Safety Board Accident Database, 2009). This increase caused the industry, and the US government, to investigate these incidents and offer recommendations to improve transport safety (Fact Sheet—FAA Initiatives to Improve Helicopter Air Ambulance Safety, 2014; Flight Safety Foundation/Aerosafetyworld, 2008). Requirements such as duty hours for pilots, weather restrictions, flight under instrument flight rules with terrain avoidance equipment, and night vision goggles can help to minimize transport risk. While ground ambulances are used much more frequently and the risk of injury and death is evident, the fatality rate is lower in ambulance accidents than it is in aircraft accidents (King and Woodward,

2002b; Becker, 2003; Becker et al., 2003). Many systems do not allow ambulances to exceed posted speed limits and allow them to use lights and sirens only as a way to identify an emergency response not to enable the vehicle to circumvent or ignore standard traffic laws (Clawson, 2002). Appropriate equipment for ambulances is required as well, and the most recent joint statement by the American College of Surgeons Committee on Trauma and the American Academy of Pediatrics regarding appropriate equipment for ambulances should be reviewed by the providers of all transport systems (American Academy of Pediatrics, American College of Emergency Physicians, American College of Surgeons, et al., 2014).

One challenge for transport teams is that differentiation of medical resources, such as a neonatal specialty team, likely means that there may be a scarcity of resources and a potential need to ration those resources. It is possible to develop teams with a variety of personnel with complementary cognitive and procedural skill sets and work toward appropriate triage of transport requests to ensure the optimal level of onsite patient care and safe transport. There have been multiple attempts to develop triage tools for pediatric and neonatal care providers, including the Mortality Index for Neonatal Transport, the Modified Clinical Risk Index for Babies, the Risk Score for Transported Patients, and the Transport Risk Index of Physiologic Stability (TRIPS) (Lee et al., 2001; Broughton et al., 2004a, 2004b; Markakis et al., 2006). Notably, TRIPS is a validated tool that can be calculated in a single assessment and has been shown to correlate with NICU mortality. The original authors of TRIPS recently validated TRIPS-II, the application of TRIPS over 12–24 hours after NICU admission, and found it correlates with illness severity not only at admission but also up to 24 hours (Lee et al., 2013). Given the simplicity and ease of use, TRIPS and possibly TRIPS-II are examples of scoring tools that can be applied in both the transport environment and the hospital environment reflecting clinical deterioration or improvement over time.

Family-Centered Care

Transport team research has shown that family-oriented care, as in other areas of health care, is an important component of transport (Woodward and Fleegler, 2000, 2001; Granrud et al., 2014; Mullaney et al., 2014; Joyce et al., 2015; American Academy of Pediatrics, 2016). Families who have been formally surveyed appreciate the opportunity to participate in the care of their child and express increased stress and anxiety when they do not accompany their child during transport (Mullaney et al., 2014; Joyce et al., 2015). In neonatal transport, however, there are times when there are two patients who may require care in two disparate locations. A mother who has had a cesarean delivery and has delivered an acutely ill neonate who requires transfer to a specialty pediatric facility with neonatal intensive care capability is one such example. Transport teams should be sensitive to the challenges and opportunities for the family members and include them in the process when possible. It is evident that when parents attend or accompany transport team members during critical care transports, they are there not to assess the medical skill set of the provider but to provide support to their child. It is also a great opportunity for the transport team to demonstrate to the family that their patient is in focused, professional, caring, and capable hands.

Medical Legal Issues

There are many medical legal issues in transport medicine, as elsewhere in the medical system (Williams, 2001; Woodward,

2003; Hedges et al., 2006; Fanaroff, 2013; American Academy of Pediatrics, 2016). The Health Insurance Portability and Accountability Act is a required component of transport planning and delivery. Discussion of patients should not happen in a public area or via public communication airways, where patient-specific information could be overheard. As noted earlier, a requirement of EMTALA is that the referring physician choose the appropriate mode of transport and ensure that the transport process and receiving hospital are appropriate for the particular patient. Patients should not be transferred if they are unstable and the ability to further stabilize them is available at the initial site of care. If a patient must be transferred for care while in an unstable condition—a frequent scenario for critically ill patients who need care not available at the referring institution—consent must be obtained from the family, which acknowledges their understanding of the potential risks and benefits of the process. In practice, there are often patients in an unstable condition who are transferred from lower to higher levels of care because the level of care that can be provided at the referring center is not optimal for the child. This reason is appropriate for transfer as compared with transfer of acutely unstable patients because of financial or other economic incentives.

The medical liability for transport is a shared process. Before the referring center contacts a receiving facility or transport team, the entire medical responsibility lies with the referring provider. Once the receiving team has accepted the patient and offered advice, medical liability becomes a shared process. The referring physician maintains most of the liability, as well as medical control of the patient, throughout the process until the transport team has left the referring hospital. It is important to recognize that most transport teams and personnel do not have privileges at referring hospitals and are working under the guidance and supervision of the referring physician team. Transport teams that act independently, or referring providers who are not available when the transport team arrives, put not only the patient but also the referring provider and transport team at risk.

There will be times, however, when there is disagreement regarding the optimal care to be delivered. This situation can be challenging, and it must be handled appropriately. It is never appropriate to have obvious provider conflict occur at a patient's bedside in front of family members. The appropriate way to handle a situation that cannot be easily mitigated is to involve the MCP with a telephone call to the referring physician in a discussion at a peer-to-peer level. Transport teams have been known to comply with the wishes of the referring providers to not perform advanced procedures at the referring hospital, only to perform those procedures in the ground or air ambulance, which is a much less desirable location. Ideally, all disagreements and considerations of different therapies should be discussed in a collegial fashion.

As noted previously, documentation of all information received and advice offered is imperative. If there is a review or there are challenges regarding the care delivered before or during transport, clear and appropriate documentation should stand alone as an excellent defense. In addition, many centers use recorded (i.e., digital, tape, other retrievable recording process) intake and advice lines; this is another way to review, educate, and ensure that appropriate information is delivered in an effective communication style. The use of recorded lines with frequent review, for educational and quality assurance purposes, can be invaluable. Review with legal advisors can help define the length of time the recorded materials should be maintained for quality improvement or patient record addendum.

Patient Care During Transport

The primary clinical goals for any neonatal transport include, but are not limited to, the following and should be established during the initial stabilization phase before departure from the referring facility and maintained until handover at the receiving facility:

- Secure and patent airway
- Adequate ventilation and oxygenation
- Thermoregulation, especially for premature neonates, goal 36°C–37°C (except as indicated for hypoxic–ischemic encephalopathy)
- Normoglycemia, goal glucose level 50–200 mg/dL
- Adequate blood pressure and perfusion
- Appropriate condition-specific care such as for myelomeningocele

A team's ability to achieve these care goals may be impacted by the patient's clinical status but will also depend on the team's preparedness and skill and experience caring for critically ill neonates. Therefore the general approach to any neonatal transport includes ensuring the availability of appropriate equipment, such as an isolette and endotracheal tubes for the smallest premature neonates, that there are skilled team members who can optimally care for a sick neonate, that there are appropriate medications for specific situations such as prostaglandin E₁ (PGE₁), and that there is smooth communication with the MCP.

Extreme Prematurity and the Limits of Viability

Of the approximately 4 million live births that occur annually in the United States, approximately 10% are preterm (<37 weeks' gestation), and approximately 1.5% are VLBW (<1500 g) (Hamilton et al., 2015). The most effective method of transporting extremely premature neonates is before delivery with the mother serving as the transport vehicle, but sometimes this is just not possible and a very premature baby is delivered unexpectedly at a referral center. Neonates born at 23–26 weeks outside tertiary centers have higher mortality and morbidity than those delivered within specialty centers (Cifuentes et al., 2002; Phibbs et al., 2007; Rautava et al., 2007; EXPRESS Group et al., 2009; Maheshwari and Luig, 2014). When delivered at a referral hospital, the premature neonate is exposed to all the variability of the extrauterine environment, with the added complexity of having to be transported to another facility capable of meeting the neonate's needs. Increased transport duration, lower gestational age, and severe acidosis before transfer have been associated with increased risk of clinical deterioration and mortality among transported VLBW neonates (Wilson et al., 2012; Arora et al., 2014). In one study the odds of deterioration increased 1.33 for every 5 minutes of transport time (Arora et al., 2014). Most neonatal transport teams are regarded as extensions of the NICU. The team initiates and provides much of the same level of complex neonatal care as the receiving hospital, but in a changing environment. It is this changing environment that poses unique challenges for both the patient and the caregiver. These issues would be amplified in the case of a natural disaster with care and transfer required for premature neonates (Gershanik, 2006; Espiritu et al., 2014).

Human viability is limited largely by the physiology of pulmonary development and currently appears to be at approximately 22–24 weeks' gestation (Pignotti and Donzelli, 2008) and 400 g (American Academy of Pediatrics, 2016). Unfortunately, for transport teams and providers at referring hospitals, it may be difficult to determine which neonates born at the margins of viability should be resuscitated and treated with aggressive neonatal care and which should not (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Buchanan, 2009). These decisions are

best made collaboratively with the family, transport team members, and the referring and receiving physicians (Tyson et al., 1996; Gunderman and Engle, 2005; Ahluwalia et al., 2008) and may ultimately result in patient transport, even when the likelihood of survival is minimal. Telemedicine may be useful to help with decision making in these difficult cases.

Thermoregulation

Problems in neonatal thermoregulation continue to be a major contributor to neonatal morbidity and mortality worldwide and can be especially problematic in neonatal transport. During transport, neonates often cross into and out of multiple different environments with wide temperature and humidity variations. Although a normal term neonate may be capable of significant homeothermic response by using its sympathetic nervous system to vasoconstrict peripherally, preterm neonates lack the subcutaneous fat insulation to protect their core temperature. Several recent studies using TRIPS found that temperature instability accounted for clinical deterioration during transport, with as many as 57% of neonates demonstrating clinical decline (Goldsmith et al., 2012; Romanzeira and Sarinho, 2015). In one study, increased mortality was observed among those neonates with clinical deterioration (Goldsmith et al., 2012). Skiöld et al. (2015) identified factors associated with temperature instability before transport and found that VLBW and the presence of respiratory support were predictors of temperature instability on arrival at the receiving center. Clearly, steps should be taken to minimize temperature instability during transport, such as adequate isolette temperature and use of chemical gel packs and polyethylene occlusive skin wrapping to help maintain temperature, especially of VLBW neonates (Vohra et al., 2004).

While humidity contributes to neonatal temperature control, especially for LBW neonates, it is also important for gas delivery among those receiving mechanical ventilator support (Sousulski et al., 1983). Ventilation with dry gases affects the airway epithelium in VLBW neonates and can result in hypothermia secondary to their large surface area to body mass ratio and their relatively large respiratory minute volume (Fassassi et al., 2007). Whereas ventilator complications can be reduced and thermoregulation can be improved by provision of exogenous heat and humidity to the gases, active heated humidification systems are used infrequently during neonatal transport. Passive hygroscopic heat and moisture exchangers have been used for short-term conventional mechanical ventilation and with some types of high-frequency ventilation (Schiffmann et al., 1997; Schiffmann et al., 1999; Fassassi et al., 2007).

For all newborns, an equally important condition to avoid is hyperthermia. Although elevated temperatures in neonates occur with increased metabolic rates, prolonged seizures, dehydration, or infection, the most common cause of neonatal hyperthermia is high ambient air temperature and humidity (Baumgart, 2008).

Surfactant

Surfactant replacement therapy has proven to be one of the most significant advances in neonatal critical care (Liechty et al., 1991; Horbar et al., 1993; Schwartz et al., 1994; Rojas-Reyes et al., 2012). Benefits are achieved with both prophylactic (defined as within 10–30 minutes of birth) and rescue (within 12 hours of birth) surfactant administration, especially for extremely LBW neonates (Kendig et al., 1991; Soll, 2000; Rojas-Reyes et al., 2012). Surfactant administration can be complicated by airway obstruction, right

mainstem bronchus or esophageal instillation, bradycardia, hypotension, and rarely pulmonary hemorrhage. These complications led the American Academy of Pediatrics Committee on Fetus and Newborn to recommend that “preterm and term neonates who are receiving surfactant should be managed by nursery and transport personnel with the technical and clinical expertise to administer surfactant safely and deal with multisystem illness” (Engle and American Academy of Pediatrics Committee on Fetus and Newborn, 2008).

Given the potential for rapid physiologic changes and the risk of complications, surfactant administration should generally not be initiated en route between facilities. While investigations are still ongoing as to the optimal manner of surfactant administration, future technology might eventually allow surfactant to be delivered without tracheal intubation. The administration of surfactant via a small intratracheal catheter while the neonate breathes spontaneously while receiving continuous positive airway pressure (CPAP), a technique known as *minimally invasive surfactant therapy* (MIST) (Kribs et al., 2007), has been shown to be equally effective as techniques involving tracheal intubation and in some studies resulted in reduced mortality and morbidity (Aguar et al., 2014; More et al., 2014; Göpel et al., 2015; Kribs et al., 2015). Several studies, including NICU-based randomized controlled trials (Rojas et al., 2009; Dani et al., 2010) have shown success with the INSURE method (Verder et al., 1994; Keszler, 2009): *intubate–surfactant–extubate* to CPAP to avoid the potential sequelae and complications of prolonged mechanical ventilation in preterm neonates. This method has not been studied in the transport environment; however, there are preliminary investigations into parameters that may serve as eligibility criteria to identify in which neonates extubation to CPAP could be safe and successful before they depart from the referring center (Priyadarshi et al., 2015). Aerosolized surfactant has yet to be shown to be superior to endotracheal tube administration (Berggren et al., 2000; Mazela et al., 2007).

Currently, the most frequently used surfactant preparations in the United States are derived from animal lung extracts. These surfactants require refrigeration and are usually carried by transport teams in small containers cooled by gel packs. Lucinactant, a synthetic surfactant, requires a special warming cradle to convert it from a gel to a liquid before administration, adding a level of difficulty to its administration during neonatal transport (Kattwinkel, 2005; Moya et al., 2005). Because smaller community hospitals may not have surfactant readily available, the transport team should carry it as part of their medical supplies.

After the surfactant has been administered, monitoring pulmonary compliance and adjusting the patient’s ventilator while still at the referring facility may extend the transport time but also limit avoidable clinical complications.

Hypoxic Respiratory Failure

Hypoxic respiratory failure describes a heterogeneous group of neonatal disorders that have in common impaired oxygenation and the need for assisted ventilation, most commonly respiratory distress syndrome, meconium aspiration syndrome, and persistent pulmonary hypertension of the newborn (PPHN). Interfacility transport of the newborn with hypoxic respiratory failure is potentially hazardous, with a high risk of patient deterioration and complications of therapy.

Assisted ventilation during neonatal transport can be accomplished with a variety of devices, although not all modes of mechanical ventilators have been modified for use in a mobile

setting. Newborns, including very preterm neonates born at 28–32 weeks' gestation with milder degrees of illness, may be managed successfully with CPAP (Murray and Stewart, 2008) with a variety of interfaces, ranging from a face mask to nasal prongs or a nasal cannula (Jani et al., 2014). A review of the limited literature (Trevisanuto et al., 2005) suggests a potential role for neonatal laryngeal mask airway during transport. This modality is particularly interesting since the success of neonatal intubation is highly variable across transport programs, specialties, and individuals. The use of sedation and neuromuscular blockade has been shown to increase intubation success (Smith et al., 2015) and is recommended by the American Academy of Pediatrics (Kumar et al., 2010). However, caution is required when considering paralytic agents if the ability to establish the airway and/or ventilate the patient is at all in question, such as with a provider inexperienced in managing a neonatal or difficult airway.

Inhaled nitric oxide (iNO) is approved for use in term and near-term newborns with hypoxic respiratory failure with clinical or echocardiographic evidence of pulmonary hypertension. Administration of iNO to newborns with PPHN reduces the need for ECMO (Clark et al., 2000; Lowe and Trautwein, 2007). With increasing availability to community NICUs, iNO therapy is often initiated before transport to a tertiary care center. Once iNO is administered, abrupt cessation of therapy can result in rapid clinical deterioration from rebound pulmonary hypertension, so it is essential to continue this therapy throughout the transport (Kinsella et al., 1995). Transport teams may also consider initiating iNO therapy for term and near-term newborns with hypoxic respiratory failure. If the referring facility does not have the capability to perform echocardiography, the transport staff should carefully consider the possibility of congenital heart lesions that can lead to clinical decompensation with iNO, including total anomalous venous return and lesions dependent on right-to-left ductal flow such as critical aortic stenosis.

The rationale for initiating iNO therapy during transport is to reduce pulmonary vasoreactivity and increase stability during transport. However, there have been no prospective studies to determine whether this practice affects patient outcome. During transport iNO has been delivered by a number of different systems, such as the aeroNOX (Aeronox Technology Corporation, Quezon City, Philippines) iNOvent, and INOmax DS (INO Therapeutics, Hampton, New Jersey, United States) transport systems (Kinsella et al., 1995; Tung, 2001; Kinsella et al., 2002; Lutman and Petros, 2008). The use of iNO in combination with high-frequency ventilation in non-ECMO centers can complicate the transfer process. If the transport team does not have the capability to provide mobile high-frequency ventilation, it is recommended that the referring hospital perform a trial of conventional mechanical ventilation before transport to establish that the neonate can tolerate the transition.

Both high-frequency jet ventilation (Bunnell ventilators; Bunnell, South Salt Lake, Utah, United States) and high-frequency flow interrupter ventilation (Bird ventilators; CareFusion, Yorba Linda, California, United States) have been configured and used with nitric oxide during transport (Honey et al., 2007; Mainilli et al., 2007). The high-frequency oscillator (SensorMedics 3100A; CareFusion, Yorba Linda, California, United States) that is commonly used in many NICUs is impractical for ground transport and is not configured for helicopter or fixed-wing transport. However, even with these technologies, the conditions of 30%–40% of critically ill neonates improve only temporarily with iNO therapy, and they will ultimately require a higher level of care (Kinsella et al., 2002; Fakioglu et al., 2005).

For patients with pulmonary or cardiac failure who are unresponsive to maximal medical therapy, conventional ECMO is often used as a bridge therapy to allow either the lungs or heart, or both, to recover. Ideally, centers without ECMO capability have prospective criteria to guide the transfer of newborns before the need for ECMO cannulation. In some cases the patient's condition is so unstable that conventional transport cannot be conducted safely. Select programs have the capability to provide mobile ECMO, during which patients are cannulated for ECMO either before transport or when the transport team arrives, in this case usually including ECMO surgical and medical specialty providers as part of the transport team. In a recent study the most common diagnoses associated with the need for neonatal ECMO transport were meconium aspiration syndrome, persistent pulmonary hypertension, sepsis, and congenital diaphragmatic hernia (Broman et al., 2015). Mobile ECMO can also benefit patients already receiving ECMO at a tertiary facility who are in need of transfer for advanced quaternary therapies, such as heart or heart–lung transplants (Wilson et al., 2002; Wagner et al., 2008; Cabrera et al., 2011). Fixed-wing and ground ambulance transport predominate as primary modalities for ECMO transport, which is logical given the size of the equipment and the team involved. In a recent study, however, 5% of ECMO transport occurred in a helicopter (Broman et al., 2015).

The resources and skill set necessary to safely and consistently perform ECMO in the transport environment have, by their complexity, restricted the number of transport programs with mobile ECMO capabilities (Coppola et al., 2008; Cabrera et al., 2011; Broman et al., 2015), and there are a limited number of centers worldwide that have long-standing, relatively high volume pediatric/neonatal ECMO transport programs. While there are no published data to set criteria for the number of ECMO transports needed to maintain competency or impact mortality, recent literature suggests that centers with at least 20–30 neonatal and pediatric ECMO cases annually have higher survival rates than centers with a lower volume (Cabrera et al., 2011; Freeman et al., 2014; Broman et al., 2015). These data support the regionalization of ECMO transport services to optimize transport team skills and performance as well as patient outcomes given the high-risk, low-frequency nature of these transports.

Neurologic Issues

Hypoxic–ischemic encephalopathy affects approximately 1 in 1000 to 2 in 1000 term neonates (du Plessis and Volpe, 2002; Shah, 2010). Several randomized trials of therapeutic hypothermia (generally sustained core temperature of 33.5°C for 72 hours) for term neonates and a recent Cochrane review have demonstrated a reduction in the combined outcome of death and neurodevelopmental disability up to 7 years of age when neonates were cooled compared with a control population (Gluckman et al., 2005; Shankaran et al., 2005; Simbruner et al., 2010; Shankaran et al., 2012; Jacobs et al., 2013; Azzopardi et al., 2014; Natarajan et al., 2014). Clinical trials and current guidelines suggest that cooling should be initiated within 6 hours of insult. For patients with a delay in referral or who are being transported from a distant center, waiting to start hypothermic therapy until their arrival at the receiving center potentially delays management shown to be beneficial. Initial larger clinical trials did not address these issues with regard to critical care transport, but several case (Anderson et al., 2007), pilot (Eicher et al., 2005), single-center studies and one recent multicenter randomized control trial (Zanelli et al., 2008; Azzopardi et al., 2009; O'Reilly et al., 2013; Akula et al.,

2015; McNellis et al., 2015) have demonstrated the feasibility and safety of controlled hypothermia during transport. Given the potential benefits of therapeutic hypothermia initiated in a timely manner, transport teams should strongly consider initiating therapeutic hypothermia, if possible, before arrival at the referral center (Box 28.2).

If the criteria for therapeutic hypothermia are met, cooling is achieved by either passive (no active warming) or active methods such as the placing of wrapped disposable cooling packs next to the trunk and head and continuous monitoring of rectal or esophageal temperature. One of the challenges is reliable temperature regulation and monitoring during the transport process with either cooling method, and it has been observed that 50% or more of neonates do not reach the target temperatures during transport (O'Reilly et al., 2011; Akula et al., 2013). A recent randomized controlled study (Akula et al. 2015) investigated the use of a servo-controlled cooling device during transport and found not only improved temperature control (target temperatures reached 89% of the time compared with 49% for traditional passive and active methods), but also therapeutic hypothermia was achieved more rapidly compared with traditional passive and active cooling methods (Akula et al. 2015). In the United Kingdom, 70% of transport teams now use servo-controlled devices, and none use non-servo-controlled active cooling methods (Sharma, 2015). Currently, the only US Food and Drug Administration approved servo-regulated cooling devices weigh between 35 and 59 kg, significantly more than the device used in the United Kingdom (6.8 kg) and also in the study by Akula et al. (2013). Considering the limitations for weight and balance on any given flight, the heavier devices could be a significant, and potentially prohibitive, addition for most flight programs.

Therapeutic hypothermia is the standard of care for perinatal asphyxia, and with additional studies reliable means of continuing or initiating this practice during transport may become clearer.

Congenital Heart Disease

Transport of the neonate with CHD follows the same general approach as for the transport of any critically ill neonate. However, neonates with complex CHD often need therapeutic intervention, requiring the support of multiple subspecialty services, including a pediatric cardiothoracic surgeon and cardiologist (Stark et al., 2000; Allen et al., 2003), which may necessitate transport to a specialized center (Castaneda et al., 1989; Penny and Shekardemian, 2001). Importantly, the preoperative care of these patients affects their postoperative outcomes and mortality (Wernovsky et al., 1995; Mahle and Wernovsky, 2000; Mahle et al., 2000; Wernovsky et al., 2000; Robertson et al., 2004; Simsic et al., 2007). In some cases the neonate will have a prenatal diagnosis of CHD and the team will have disease-specific management plans, for instance, initiation of PGE₁ therapy on arrival for a neonate with a clinically stable ductal-dependent lesion. In other cases, CHD may be suspected in a critically ill neonate with signs of cardiovascular collapse, and the transport team must be prepared to initiate treatment, such as PGE₁ therapy, or limit others, such as treatment with fluids and oxygen, to manage a potential but not yet confirmed diagnosis. Regardless of whether the presence of CHD is known or suspected, the transport team must be prepared to manage it.

To optimize management, early communication with the receiving specialty center is vital. Successful transport involves two phases: referring hospital staff to the transport team and subspecialists and referring transport staff to the accepting hospital

• BOX 28.2 Criteria for Neonatal Therapeutic Hypothermia on Transport

1. Patient *must* meet the following:
 - ≥ 36 weeks' gestation
 - Birth weight >1800 g
 - Less than 6 h of age
 - First-hour blood gas, if available: pH ≤ 7.15 and base deficit ≥ 10
 - No severe congenital anomaly
 - Plan for continued full care
 2. Criteria additional to above eligibility:
 - And first-hour blood gas: pH ≤ 7.0 or base deficit or base deficit ≥ 16
 - Or no blood gas available or first-hour blood gas: pH 7.0–7.15 or base deficit 10–16
- And both:*
- 10-min Apgar score ≤ 5 or assisted ventilation at birth ≥ 10 min
 - Acute perinatal event
 - Intrauterine distress
 - Cord rupture or prolapse
 - Uterine rupture
 - Maternal trauma/hemorrhage
 - Cardiopulmonary arrest
3. *And either of the following:*
 - Moderate to severe encephalopathy
 - Seizures

staff. The need for precise and thorough communication between respective teams cannot be overemphasized. Whenever possible, the pediatric cardiologist, neonatologist, or intensivist at the accepting hospital should be included in formulating the transport management plan while the neonate is still at the referring hospital, thereby guiding the timing and urgency of the transport, line placement, and recommendations for airway management and supplemental oxygen therapy (Table 28.2).

The neonatal resuscitation algorithm is applicable in the presence of CHD (Johnson and Ades, 2005) but should be modified in certain circumstances. In presentations with hypoxemia that is unresponsive to supplemental oxygen, congestive heart failure, or shock, simultaneous attention is devoted to the basics of neonatal advanced life support and to assurance of a patent ductus arteriosus.

A stable airway must be maintained, allowing adequate alveolar oxygenation and ventilation before transport. In critically ill neonates with known CHD presenting with severe cyanosis or circulatory collapse, intubation should be performed by a skilled provider after premedication with sedation and neuromuscular blockade. Reliable venous access is important, and arterial monitoring is helpful for ongoing assessment of blood pressure, acid–base status, and gas exchange. Volume resuscitation, inotropic support, and correction of metabolic acidosis may be required to maximize cardiac output and tissue perfusion. In neonates with suspected but not confirmed CHD, an evaluation for sepsis is typically considered simultaneously, and empiric antibiotic therapy is initiated.

Supplemental Oxygen

Supplemental oxygen is a potent pulmonary vasodilator and systemic vasoconstrictor, and it can adversely affect the physiology of neonates with a single ventricle, as well as those with two ventricles with an unrestrictive ventricular septal defect or great vessel communication. The oxygen-induced pulmonary vasodilation can decrease pulmonary vascular resistance and increase pulmonary blood flow at the expense of systemic blood flow, thus reducing systemic output in some cases. For known CHD, the use of oxygen therapy and goal oxygen saturations should be determined with the use of established guidelines for specific lesions or in consultation with an MCP. Titrating oxygen via a nasal cannula or face mask to a target peripheral saturation of 75%–85% usually corresponds to adequate blood flow in both the pulmonary system and the systemic system. Higher oxygen saturations are typically not necessary and in fact may ultimately result in decreased oxygen delivery to the peripheral tissues. In cases of undifferentiated neonatal hypoxemia where CHD is suspected, oxygen therapy should be continued until CHD is ruled out by echocardiogram since severe pulmonary hypertension is also in the differential diagnosis and supplemental oxygen therapy is indicated.

Prostaglandin E₁ Therapy

PGE₁ therapy is the standard of care for stabilization of known ductal-dependent CHD (DDCHD) but is often initiated in undifferentiated hypoxic neonates when DDCHD is possible but not confirmed. In a study examining the diagnostic accuracy for CHD based on the clinical findings of a transport team, [Gupta et al. \(2014\)](#) found that there was no single finding predictive of DDCHD, concluding that making this diagnosis outside a specialty center was challenging. In a separate study, the same authors ([Gupta et al., 2013](#)) studied the effects of PGE₁ administered to both neonates with DDCHD and those with PPHN and found that when PGE₁ was administered to neonates with persistent pulmonary hypertension, they recovered faster and no adverse events were observed during transport.

In the instance of prenatally diagnosed CHD, ductal dependency is often already determined. In these cases, maintaining ductal patency is key. Whenever possible, PGE₁ infusions should be prepared ahead of arrival at the referring center and started promptly. PGE₁ may be given via a central or peripheral intravenous catheter or in emergent situations where intravenous access cannot be obtained via an umbilical catheter or intraosseous line. For neonates with suspected CHD whose duct has begun to close, usually after the first 24 hours of life, PGE₁ is often required and response is immediate if ductal patency is central to the hemodynamics of the neonate. In all cases, failure to respond to appropriate dosing may mean that the initial diagnosis of DDCHD is incorrect, the ductus

Side effects of therapy with prostaglandin E₁ in infants with critical congenital heart disease. *Circulation*. 1981;64:893–898; Arav-Boger R, Baggett HC, Spevak PJ, Willoughby RE. Leukocytosis caused by prostaglandin E₁ in neonates. *J Pediatr*. 2001;138:263–265; and Teixeira OHP, Carpenter B, MacMurray SB, Vlad P. Long-term prostaglandin E₁ therapy in congenital heart defects. *J Am Coll Cardiol*. 1984;3:838–843.

is unresponsive to PGE₁ therapy (which may occur in older neonates), or there is no ductus arteriosus present. Often the condition of the patient with a ductal-dependent lesion will improve greatly with the initiation of PGE₁ therapy, and the patient may not need to be rushed to the cardiac referral center as an emergent case.

On rare occasions, the neonate may have progressive instability after initiation of PGE₁ therapy. This important diagnostic finding strongly suggests a congenital heart defect with obstructed blood flow out of the pulmonary veins or the left atrium.

The following are types of CHD unresponsive to PGE₁ therapy:

- Hypoplastic left-sided heart syndrome with a restrictive foramen ovale or intact atrial septum
- Variants of mitral atresia with a restrictive foramen ovale
- Transposition of great arteries with an intact ventricular septum and restrictive foramen ovale
- Total anomalous pulmonary venous return with obstruction of the common pulmonary vein

If the neonate clinically deteriorates despite receiving PGE₁ therapy, urgent echocardiography is indicated, followed by prompt transfer to a cardiac unit ([Penny and Shekerdeman, 2001](#)). Controversy exists as to whether PGE₁ therapy should be continued in these rare instances, but most importantly, the apparent lack of response is a marker for rare forms of CHD that do not respond to medical management and require urgent surgical or catheter intervention.

Although PGE₁ is critical in the management of DDCHD, there are a number of potential adverse effects associated with PGE₁ that must be anticipated, particularly in the premature neonate, in which they occur more commonly ([Table 28.3](#)). Apnea and hypotension usually manifest themselves during the first few hours of administration but can occur at any time during the infusion. Judicious fluid resuscitation will generally normalize the blood pressure in cases of hypotension ([Kramer et al., 1995](#)). If hypotension is refractory to fluid administration, an alternative cause of hypotension should be considered (e.g., a restrictive ductus, pericardial effusion, myocardial dysfunction, sepsis), and inotropes should be prepared. Hypotension is a late finding in neonatal cardiogenic shock and ideally should be managed before transport during the stabilization phase.

The potential side effect profile of PGE₁ mandates the need for ongoing cardiorespiratory monitoring during transport; however, it does not in and of itself usually require intubation and mechanical ventilation without the presence of significant or recurrent apnea ([Kramer et al., 1995](#); [Browning Carmo et al., 2007](#)). Low-dose PGE₁ infusions are unlikely to cause apnea requiring mechanical

TABLE 28.4 Features of High-Lying Versus Low-Lying Umbilical Artery Catheters

| High | Low |
|--|---|
| <ul style="list-style-type: none"> • Catheter tip above diaphragm, below left subclavian artery, ~T6–T10 • Decreased risk of vascular complications • No significant increase in adverse sequelae | <ul style="list-style-type: none"> • Catheter tip below renal arteries, above aortic bifurcation, ~L3–L5 |

Data from Barrington KJ. Umbilical artery catheters in the newborn: effects of position of the catheter tip. *Cochrane Database Syst Rev*. 2000;(2):CD000505; and Hermansen MC, Hermansen MG. Intravascular catheter complications in the neonatal intensive care unit. *Clin Perinatol*. 2005;32:141–156.

ventilation, and neonates can be safely transported without an artificial airway being established in most cases (Carmo and Barr, 2005).

Vascular Access

Umbilical venous catheters and umbilical arterial catheters are useful in the stabilization and transport of critically ill neonates, including those with CHD. However, there is a time window in which each of the vessels can be accessed: typically, an umbilical venous catheter (UVC) can be placed up to 1 week of age, while placement of an arterial catheter is challenging beyond approximately 72 hours. In addition, placement of these lines is not without risk. Beyond the infectious risks, newborns with CHD are at a higher risk of thromboembolic events because of their underdeveloped clotting mechanisms, small-vessel lumens, and low flow states. There is also an ongoing risk of systemic embolization of air and particulate matter in babies with an intracardiac right-to-left shunt. There has been much controversy surrounding the optimal placement of an umbilical arterial catheter (UAC) in premature neonates, although there are scant data regarding term neonates with CHD (Table 28.4).

Catheter levels between high and low designations are associated with increased risks of complications, as are placements below the L5 level (Hermansen and Hermansen, 2005). The UVC should be placed, if possible, at the inferior vena cava/right atrial junction or in the atria. It might not be necessary to obtain ideal placement of either the UAC or the UVC for stabilization and transport, and manipulation of lines and reconfirmation can delay transport to the tertiary care center. The risk–benefit relationship for the use of umbilical lines in the neonate with ductal-dependent circulation has not been well delineated. The need for central access should be judged on the basis of the clinical status of the neonate and stability for transport.

Surgical Emergencies

Because most births occur in hospitals without a NICU or neonatal surgical services, the need for surgical evaluation or intervention is a common reason for interfacility transport. Whereas some surgical conditions are relatively nonurgent, there are several diagnoses that represent truly life-threatening conditions for which stabilization and transport require expertise and specialized resources.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) presents along a spectrum of severity, is associated with pulmonary hypoplasia

and hypertension, and can be isolated or accompanied by other congenital malformations. Advances in ultrasound technology have resulted in prenatal diagnosis in up to 60% of fetuses with CDH (Gallot et al., 2007). A recent systematic review showed that outcome was improved for newborns in whom CDH was diagnosed prenatally or who were born in a tertiary care center (Logan et al., 2007b). Newborns with undiagnosed CDH are at high risk of complications.

The following are important in the transport of critically ill neonates with known or suspected CDH (Logan et al., 2007a, 2007b; Grisaru-Granovsky et al., 2009):

- Secure the airway with endotracheal intubation if respiratory distress is present.
- Ventilation approach: gentle ventilation
 - Allow permissive hypercapnia.
 - Limit peak airway pressures.
 - Use low tidal volumes.
 - Allow spontaneous breathing as much as possible, with judicious use of sedation and neuromuscular agents.
- Decompress the bowel with a nasogastric or orogastric tube connected to low intermittent suction.
- Maintain adequate systemic blood pressure with fluid and inotropes as needed.

Although there is still controversy over the role of ECMO for newborns with CDH, transport to a high-volume center with ECMO capabilities should be strongly considered (Grushka et al., 2009; Morini et al., 2006).

Abdominal Wall Defects

The proper management of a newborn with gastroschisis or an omphalocele is critical during the first several hours of life, and delivery in a tertiary care center has been associated with improved outcome (Quirk et al., 1996). In addition to the need for initial resuscitation and cardiorespiratory support, the correct treatment of the exposed bowel or sac may improve the newborn's chances of a successful repair and long-term intestinal function.

While current guidelines aim for at least 38 weeks' estimated gestational age for elective cesarean delivery, previously, the mean gestational age for newborns with gastroschisis was 36.6 weeks (Lausman et al., 2007). Many affected neonates are small for their gestational age (Baerg et al., 2003), and as with other mildly premature and growth-restricted neonates, patients with gastroschisis are at risk of hypothermia and hypoglycemia. Heat loss is exacerbated by the large surface area of the exposed intestines, which can also serve as a significant source of fluid loss. Prevention of heat and fluid loss can be accomplished by placement of the lower part of the neonate's body, including the intestines, into a transport bag (i.e., bowel bag or Lahey bag) before placement of the neonate into the heated transport isolette. Significant fluid losses can occur through the exposed mucosa, and the patient may require aggressive fluid replacement (120–150 mL/kg per day). The use of antibiotics should be considered if risk factors for sepsis are present after review with a pediatric surgeon.

Neonates with gastroschisis are at risk of intestinal vascular compromise, because the vascular pedicle containing the arterial supply and venous drainage from the bowel must pass through the relatively small abdominal wall defect. Transport personnel must closely monitor the appearance of the bowel to detect signs of venous congestion or ischemia. Transporting the neonate in the lateral position, with support of the exposed intestines to avoid tension or torque, is recommended. The use of intestinal pulse oximetry has been described for monitoring the bowel for ischemia

through a transparent silo but has not been studied as a tool during interfacility transport (Kim et al., 2006). Vascular compromise of the intestine is a surgical emergency, and communication with the receiving facility is essential to coordinate urgent intervention.

The transport of a neonate with an omphalocele has similar considerations, although unless the sac has ruptured, there is minimal risk of heat and fluid loss. Neonates with an omphalocele are more likely than those with gastroschisis to have other birth defects (e.g., CHD). Furthermore, neonates with giant omphaloceles often have respiratory insufficiency caused by diaphragmatic dysfunction, pulmonary hypoplasia, or both and may require ventilatory assistance.

All neonates with gastroschisis or an omphalocele require placement of a large-bore nasogastric or orogastric tube because of the functional ileus or intestinal obstruction that may occur with associated stenoses or atresias. In general, cannulation of the umbilical vessels is not recommended unless other methods for vascular access are not successful.

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia, with or without tracheoesophageal fistula, is typically diagnosed within the first day of life because of increased secretions, poor feeding, and respiratory distress. General transport considerations include placement of a large-bore sump-type tube for continuous aspiration of the proximal esophageal pouch, positioning (prone with the head of the bed elevated), and respiratory support as indicated. Direct aspiration of secretions into the trachea may occur with either a proximal or a distal tracheoesophageal fistula. Transport providers should be aware that neonates with a distal tracheoesophageal fistula (type C), characterized by the presence of air in the intestinal tract, are at risk of gastric and intestinal insufflation via the fistula when receiving positive pressure ventilation. Bag-mask ventilation and CPAP should be avoided. If the neonate requires endotracheal intubation, the endotracheal tube should be positioned as close to the carina as tolerated in an effort to position the distal tip beyond the fistula and minimize direct inflation of the distal esophageal segment with pressurized gas. In extreme cases, gastric rupture with pneumoperitoneum has been reported, requiring emergency paracentesis, laparotomy, or both (Maoate et al., 1999).

Midgut Volvulus

Malrotation with midgut volvulus can be a catastrophic event resulting in intestinal ischemia and shock and represents a surgical emergency. The most common clinical presentation of midgut volvulus is bilious vomiting, which is a nonspecific sign of intestinal obstruction. Expedient evaluation of the newborn with bilious vomiting is essential to facilitate prompt surgical intervention to prevent progression of vascular insufficiency to actual intestinal necrosis. An upper gastrointestinal tract series is the radiologic test of choice to diagnose malrotation and midgut volvulus, although some practitioners have reported success with the use of ultrasound examination to identify the relationship of the superior mesenteric vessels (Lampl et al., 2009; Shew, 2009).

A neonate with suspected midgut volvulus should be rapidly cared for in a facility with pediatric radiology and surgical capabilities. Care of the neonate with suspected midgut volvulus during interfacility transport is primarily supportive and includes circulatory interventions with intravenous fluid repletion, correction of metabolic abnormalities, and gastric decompression with a large-bore nasogastric or orogastric tube.

Necrotizing Enterocolitis

Necrotizing enterocolitis is relatively common in premature neonates, and approximately 30% of newborns with necrotizing enterocolitis will require surgical intervention in the form of laparotomy or peritoneal drain placement (Guthrie et al., 2003). Neonates with moderate or severe necrotizing enterocolitis should be transported to a facility with pediatric surgical capabilities. Care during transport is primarily supportive and includes intravenous fluids, administration of broad-spectrum antibiotics, correction of metabolic abnormalities, and gastric decompression. Respiratory failure is common because of disordered control of breathing and elevation of the diaphragm from abdominal distention. With significant free intraperitoneal air or pneumatosis and changes in altitude, neonates may be at risk of intra-abdominal hypertension and abdominal compartment syndrome. Transport providers should be aware of this and discuss potential interventions, such as a peritoneal drain, with the MCP and referring provider before departure from the referring facility. Abdominal decompression before transport has been previously recommended for the transport of neonates with pneumoperitoneum (McAdams et al., 2008).

Meningomyelocele

Although in most newborns with neural tube defects diagnosis is prenatally because of an elevated alpha fetoprotein level, and they are therefore delivered in a tertiary care center, the unexpected birth of a baby with a meningomyelocele may be an indication for neonatal transport. For purposes of transport, the newborn should be placed in the prone position, and the spinal defect should be covered with moist sterile dressings as well as some form of plastic wrap to maintain moisture. The lesion can be covered with a moistened nonadherent dressing and then loosely encircled with a gauze roll “donut,” with the entire defect covered with a sterile drape. This dressing can be moistened as required during the transport process (Jason and Mayock, 1999). The use of latex gloves should be avoided during care of these patients. If cerebrospinal fluid leakage is observed or suspected, there is an increased risk of infection, and empiric antibiotics should be considered. Neonates with a meningomyelocele may or may not have accompanying hydrocephalus at birth; approximately 25% of affected patients will require shunting in the immediate newborn period, with up to 85% eventually undergoing shunt placement (Bowman et al., 2001). In one institution, the percentage of patients necessitating shunt placement was reduced when stricter criteria were used, including permissive mild ventricular dilatation and the presence of symptomatic hydrocephalus (Chakraborty et al., 2008). Furthermore, the results of the Management of Myelomeningocele Study, which demonstrated reduced need for shunt placement and corresponded with improved neurologic and motor outcomes at 30 months (Adzick et al., 2011) following in utero repair of the spinal defect, may lead to additional practice changes in postnatal shunt placement.

Future Directions

The field of transport medicine has grown substantially in the past several decades and will continue to grow and change, particularly in relation to special and vulnerable patient populations. The goals include rapid awareness of need, clear communications, and delivery of care that is similar to that in our level III/IV NICUs. Development of standards and guidelines will enable us to assess the impact of neonatal transport and the opportunity it provides for patients and clinicians. The role of developing technologies, such as

telemedicine, will likely have an increasing presence in referral hospitals as well as for use by transport teams. In addition, there will likely be increasing attention paid to cost and value, especially of high-cost air transport, that may lead to stricter criteria and a greater push toward national transport guidelines, and potentially even drones may play a role at least in equipment and medication delivery to outlying hospitals. The transport of critically ill neonates is most often a high-risk, low-frequency event in the context of all patient transfers. Therefore as systems move forward, it is imperative to ensure the highest level of skill and competence both in the transport team and in the facilities that refer and receive these patients be it through team specialization, regionalization of high-level neonatal critical care, or support of telemedicine and outreach initiatives. Most likely it will be achieved through all of these.

Temperature Regulation

W. ALAN HODSON

KEY POINTS

- Providing an appropriate and stable thermal environment is important for newborns regardless of size or gestational age.
- The thermal neutral environment (TNE) refers to the ambient temperature necessary to maintain normal metabolism.
- Newborn (admission) hypothermia continues to be a global challenge, particularly in resource-limited settings.
- Radiant warmers, warm blankets or thermal mattresses, head covering, plastic wrap (without drying), delayed bathing, and skin-to-skin care have been recommended to reduce neonatal hypothermia.
- Interhospital transport, particularly for critically ill and/or very-low birth weight (VLBW) neonates, increases the risk of thermal instability.

All newborns are at risk of experiencing cold stress. Providing an appropriate and stable thermal environment is important for newborns regardless of size or GA. Most of the temperature needs of the full-term infant will be associated with birth or in rare circumstances with the development of an illness or instability. It is imperative that providers involved with delivery or subsequent care understand the various causes and consequences of heat loss, the mechanisms of heat production by the infant, and the multiple management options for providing the correct thermal environment. A variety of different clinical conditions present different management challenges depending on the degree of immaturity, birthweight, and concurrent illness such as respiratory distress, sepsis, or asphyxia. Temperature regulation is an essential and important component of neonatal intensive care.

More than 50 years ago and before the development of intensive care nurseries, research demonstrated an association between temperature control and increased survival in premature infants. Incubators first appeared in the 19th century in Europe, but it was not until the 1930s that they were incorporated into the care of premature infants at Michael Reese Hospital in Chicago. However, the concept that premature infants were unharmed by hypothermia (acting as if they were similar to a poikilothermic animal) prevailed until controlled trials (Silverman et al., 1958) demonstrated the associated morbidity and mortality of cooling in various birthweight groups. A number of studies (Karlberg, 1962; Day et al., 1964; Scopes and Ahmed, 1966; Dahm and James, 1969; Hey, 1969) demonstrated the metabolic cost of cold stress, resulting in a doubling or tripling of oxygen consumption, particularly in

early-gestation infants. These studies were the first attempts at defining the optimal environmental temperature resulting in a normal body temperature—the so-called *thermal neutral environment* (TNE). This quest has resulted in ever-increasing refinements of protective management techniques, including hybrid incubators, radiant heaters, heated gel mattresses, plastic wrapping, heat shields, a laminar flow device, clothing, caps, room temperature control, and protocols for intermittent skin-to-skin care (SSC). The appropriate incorporation of the many management options will depend on the needs of individual babies related to their birthweight, maturity, degree of illness, and postnatal age.

Mechanisms of Heat Loss

The most vulnerable time for heat loss occurs during the first minutes after birth. It is of interest to consider the thermal environment of the fetus and how a stable body temperature is maintained despite variations in fetal metabolic activity associated with sleep cycles, muscular activity, respiratory movements (fetal breathing), and changes in maternal temperature. Periods of “heat excess” probably occur as maternal temperature varies; the fetal temperature follows closely and maintains a differential of approximately 0.5°C above maternal temperature. What is the mechanism of fetal heat transfer? It is estimated that 85% of heat exchange occurs through the placenta, and the remaining 15% occurs through conduction from the skin to amniotic fluid and then to the uterine wall (Rudelstorfer et al., 1981). The heat flux across the skin will increase if there is compromised placental function. Significant elevations in maternal temperature have the potential to cause fetal harm, hence the standard advice given to pregnant women to avoid hot tubs. Maternal fever as a result of inflammation or infection is most likely of higher risk to the fetus than maternal exercising or ambient heat stress. The temperature gradient between the fetus and the mother may increase beyond 0.5°C during labor or uterine contractions and widens slightly with advancing GA.

There are four major mechanisms of heat loss that will vary over progressive days of nursery care (depending on the maturity of the baby, growth, illness, and environmental factors). These include evaporation, radiation, convection, and conduction, each with variable contributions to the heat loss (Table 29.1).

Evaporation

The evaporative losses at birth may result in a fall of 2°C–3°C within the first 30–60 minutes after birth if the newborn is extremely

TABLE 29.1 Four Major Mechanisms of Heat Loss in Newborns: Estimated Percentages of Each, Based on the Environmental Temperature

| | ENVIRONMENTAL TEMPERATURE | | |
|-------------|---------------------------|------|------|
| | 30°C | 33°C | 36°C |
| Radiation | 43% | 40% | 24% |
| Convection | 37% | 33% | 5% |
| Evaporation | 16% | 24% | 56% |
| Conduction | 4% | 3% | 1% |

TABLE 29.2 Relative Skin Surface Area in the Adult and in Low Birth Weight Infants

| | Relative Skin Surface Area (cm ² /kg) |
|---------------|--|
| Adult | 250 |
| 1500-g infant | 870 |
| 1000-g infant | 1000 |
| 500-g infant | 1400 |

premature or no wrapping, drying, or clothing is applied in a larger newborn. Delays in warming may occur if resuscitation or other medical care delays drying. The first minutes after birth are already stressful because of the physiologic adaptations for the onset of breathing, absorption of fetal lung fluid, circulatory changes, and the transient drop in arterial partial pressure of oxygen below 15 Torr.

The major heat loss from evaporation is due to exposure of the large surface area of wet skin relative to the baby's body mass and to the duration of exposure while naked and wet from the amniotic fluid. The more immature the newborn, the larger the relative surface area (Table 29.2). In full-term newborns the evaporation of water from the skin decreases until a body temperature of 36.6°C–37.1°C is reached. The concomitant increase in skin blood flow does not appear to influence evaporative heat loss.

Insensible water loss through the skin continues to contribute to evaporative heat loss and decreases over the first few days after birth. The rate of evaporative water loss depends on the ambient humidity and increases at humidity levels below 50%. Evaporation is somewhat greater under a radiant heater compared with an incubator. Studies have demonstrated large losses from transepidermal water loss (evaporative) over the first few days after birth in extremely low birth weight newborns (Fig. 29.1). This suggests that the skin permeability of these very premature neonates, especially during the first hours after birth, is very different from that of neonates born beyond a GA of 34 weeks (Hammarlund and Sedin, 1982).

Radiation

Radiation is a major source of heat loss, so it has been the focus of most research studies and has led to the development of many devices to minimize that loss and to protect the infant from excessive energy expenditure. Radiant heat loss from the skin can be

• **Fig. 29.1** Transepidermal water loss in relation to gestational age at birth and at different postnatal ages in appropriately grown infants. (Redrawn from Sedin G, Agren J. Water and heat—the priority for the newborn infant. *Ups J Med Sci.* 2006;111:45–59.)

responsible for 40% or more of the daily heat loss (when air movement is low). Many variables can influence the degree of heat loss, including body surface area, environmental temperature, the type of external heat source, clothing, blankets, caps, heat shields, and swaddling. The full-term infant should not present ongoing concerns with radiant heat loss if commonsense measures of care are provided, including a room temperature of 24°C–26°C, appropriate SSC, clothing, and blankets. Premature infants and those who are undergrown or ill with cardiorespiratory distress, sepsis, asphyxia, or other disorders will be at continued risk of radiant heat losses. This mechanism of heat loss is influenced by the mean temperature of the skin and the mean temperatures of the surrounding walls, as well as the temperature gradient to a nearby object of lesser warmth and temperature even if the object is outside but near the incubator or the warmer.

Convection

Heat loss due to convection is determined by the airflow around the infant, the mean temperature of the ambient air, the mean temperature of the skin, and the exposed surface area of the infant. Different incubators have different airflow, humidity, and wall temperature capacities that can influence the degree of convective heat loss.

Conduction

Conductive heat losses contribute minimally to energy expenditure and depend on the thermal conductivity of the mattress, which is low in incubators and under radiant warmers. Skin adjacent to a colder object such as an X-ray plate or other cold instruments will result in some conductive heat loss.

Mechanisms of Thermoregulation

How does the infant sense temperature? Does the newborn have sensing mechanisms similar to those of the adult, and are there comparative developmental changes in the relative contribution

from skin or central nervous system receptors in the extremely premature infant and the full-term infant? Temperature sensors are located in the skin at many sites. Some are more dominant than others in influencing the infant's heat production. More information is needed on the relative contribution of peripheral versus central temperature receptors in controlling core temperature.

The optimal temperature for a specific infant cannot be defined by a single central temperature; rather, it is defined by the range of measurable skin temperatures that are associated with minimal heat production. This implies an optimal central or core temperature. The recommended range for normal rectal and axillary temperatures is 36.5°C–37.5°C for full-term infants, 35.6°C–37.3°C for preterm infants, and 36.7°C–37.3°C for very low birth weight (VLBW) infants. Measurement sites include the axilla, rectum, and skin. The small size of the ear canal precludes tympanic measurement. Axillary temperature measurement is intermittent, with minimal errors related to placement of the thermometer, and rectal temperatures have a risk of trauma and inaccuracies because of the depth or duration of insertion as well as passage of stool. Continuous temperature monitoring with an infrared skin probe placed over the midline of the upper abdomen or on the back below the scapulae permits accurate assessment of core temperature under various external heating arrangements.

The “thermal neutral zone” or TNE refers to the ambient temperature necessary to maintain normal metabolism. For the average naked adult it is 25°C–27°C, and for the full-term naked newborn it is 32°C–34°C (Hey, 1970). For premature infants it will differ with GA. Infants of a GA of 25 weeks or less will require an ambient temperature close to that in utero (i.e., 35°C–37°C) until they are placed in an appropriate protective environment. The tiniest infants are more susceptible to temperature instability because of the absence of subcutaneous fat for insulation, decreased levels of brown fats, large body surface area to body weight, poor vasoconstrictor control, decreased spontaneous muscle activity, increased evaporative losses, and transepidermal insensible water loss. Small for GA infants will have a higher metabolic rate for weight. An increase in activity and ingestion of food in growing preterm infants will increase metabolic rate through altered energy expenditure.

Nonshivering Thermogenesis

Since the newborn is unable to reduce heat loss or increase heat production by shivering or increasing voluntary muscle activity, nonshivering thermogenesis produces energy output and hence heat production through the oxidation of fatty acids, largely from brown fat. Glucose or glycerol appears to be an alternative fuel utilized for this purpose. Brown fat comprises most of the fat content of the newborn. Brown fat deposits have been located in six major sites (Merklin, 1974) and show increased oxidation within minutes of birth (Fig. 29.2). It appears as early as 25 weeks in the fetus but is probably not an efficient participant in thermogenesis at this stage of development. Temperature receptors sensing a low temperature stimulate increased sympathetic output from the central nervous system, resulting in norepinephrine release, which in turn stimulates β -adrenergic receptors in brown fat, increasing cyclic AMP production (Hull and Seagall, 1965). A major uncoupling protein (thermogenin) is found exclusively in brown fat. The release of cytoplasmic stores of triglycerides and fatty acids increases metabolism, resulting in increased oxygen consumption and heat production. Other endocrine factors such as thyroxine,

• **Fig. 29.2** Distribution of brown fat deposits in the newborn from 28 to 42 weeks' gestation. (Redrawn from Aherne W, Hull D. The site of heat production in the newborn infant. *Proc R Soc Med.* 1964;57:1172–1173.)

• **Fig. 29.3** Variations in metabolic rate with changes in environmental temperature in human newborns, including the thermal neutral zone and extremes of cooling and heating. (Redrawn from Baumgart S. Incubation of the human newborn infant. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the Clinician*. Norwalk: Appleton and Lange; 1993:139–150.)

triiodothyronine, and thyroid-stimulating hormone may play a role in this process, but further study is needed (Houstek, 1993).

During the 1960s, considerable clinical and animal research helped to define the TNE for newborns in relation to changes in environmental and core temperatures. Environmental temperatures were progressively decreased below 34°C in experiments that resulted in a steady increase in oxygen consumption to values that were two to three times the resting value. If environmental cooling exceeds the infant's thermoregulatory response of energy output, the core temperature will drop along with a decrease in oxygen consumption (Fig. 29.3). This “ Q_{10} effect” of decreased metabolism when the environmental temperature falls below a critical point is the basis for the use of induced hypothermia in other clinical situations. The increase in oxygen consumption and the increase in metabolic output are considered important contributors to increased morbidity and mortality especially in extremely low birth weight infants. Extended periods of cold stress have been

associated with hypoglycemia, respiratory distress, hypoxia, metabolic acidosis, necrotizing enterocolitis, and death.

Thermal Management Strategies

Understanding the many causes of heat loss and the resulting response of nonshivering thermogenesis with the consequences of cold stress have led to a variety of protective and therapeutic options. Much controversy has arisen about various warming devices and techniques, resulting in new or modified equipment and strategies. The goal of estimating and maintaining the TNE for each infant is supported by evidenced-based trials. The indication and timing of interventions have resulted in management protocols applicable to various clinical settings, including transport, delivery rooms, full-term nurseries with “rooming-in” policies, and neonatal intensive care units (NICUs).

Delivery Room Environment

Hypothermia soon after birth has been associated with increased morbidity and mortality, prompting organizations such as the Neonatal Resuscitation Program and the World Health Organization to stress the importance of preventing early postnatal hypothermia (Lapcharoensap and Lee, 2016). The maternal temperature at delivery should be noted on the baby’s birth record, along with an axillary temperature. The room temperature should be kept at 28°C. Ideally, a preheated gel mattress, with a warm bassinet, warm blankets, and a radiant heat source should be in place. Immediate drying, swaddling (once stabilized), and placement of a cap will reduce evaporative heat loss. The full-term newborn will maintain a normal body temperature with appropriate clothing and blankets in an environment of at least 24°C. Preterm newborns need additional protection from heat losses, including higher ambient temperature and the use of plastic wraps (without drying). Early SSC, once the infant has been stabilized, can be very effective in preventing hypothermia—particularly in resource-limited settings.

Delayed umbilical cord clamping in very preterm newborns has raised concern regarding thermal management. However, a metaanalysis of several studies done in newborns of less than 32 weeks’ GA was reassuring, with no differences noted in admission temperature (Backes et al., 2014).

Care of the Extremely Low Birth Weight Infant

The neonate born before 28 weeks’ gestation presents a major challenge in the prevention of heat loss. Hypothermia is reported to occur in the most extremely low birth weight neonates on their admission to an NICU and is especially hard to prevent in neonates born at less than 25 weeks’ gestation. Furthermore, it is associated with an increased risk of early and late neonatal death (Wilson et al., 2016). Recent studies support the use of plastic bags and caps in the delivery room (Knobel et al. 2005). The newborn is placed immediately in a plastic bag up to the neck without drying and placed under a radiant warmer. The head is dried and covered with a plastic cap. Resuscitation can proceed with the bag in place. This provides initial stability for transfer to the NICU or transport to another facility. The first 12 hours is important in preventing further heat loss. Possible contributors to cold stress are the temperature of the inspired airflow, evaporative loss under radiant heat, cold hands, weighing scales, the temperature of intravenous infusions, fluid boluses within syringes, and intervention procedures such as intubation, X-rays, and vessel cannulation.

The duration of vessel cannulation determines the length of time the newborn is covered with a sterile drape and will interfere with warming. Expediency is therefore important in completing this procedure.

Warming Babies

Both incubators and radiant warmers have been in use in NICUs for several decades and remain the focus of heat management. Each of these warming devices has undergone sophisticated evolution and remains effective in providing a TNE for infants of differing sizes and with differing illnesses. Both provide enhanced observation and access when needed. There are slight differences between incubators and radiant warmers in the degree of evaporative and radiant heat loss, but no significant differences in outcomes have been demonstrated.

Incubators Versus Radiant Warmers

The prototype of the modern incubator, using the principal of convective heating of air, came into widespread use in nurseries in the 1960s. Since then there have been many modifications allowing precise control of air temperature, airflow, humidity, and limitation of heat losses due to convection, radiation, and conduction within the incubator (Antonucci et al., 2009). Comparisons of single-walled and double-walled incubators have shown that both are effective, with appropriate monitoring. There are three options to achieve a stable and desirable skin temperature of 36.0°C–36.5°C:

1. Servo control of incubator air temperature
2. Servo control of abdominal skin temperature (using an abdominal skin probe)
3. Manual control of incubator temperature with knowledge of abdominal skin temperature

The advantage of servo control with an abdominal skin probe is that it ensures maintenance of a constant body temperature despite perturbations caused by a decreased environmental temperature from open portholes or opening of the incubator top. Overheating can occur if the probe becomes detached or covered with a blanket.

Heat shields and thermal blankets have been used over the infant within the incubator and can reduce insensible water and radiant heat loss. Heat shields will not increase metabolic rate and do not need to be used with single-walled incubators. The rationale for creating the double-walled incubator was to reduce heat loss. Several studies demonstrate small differences in heat loss and heat production and have not shown a difference in clinical outcome if skin temperature servo control is used (Deguines et al., 2012).

Overhead radiant heaters were first used in delivery rooms, particularly for support during resuscitation procedures. They then evolved into the Sieracin Cradle Warmer, which fit over an open bassinet. This warmer was used to observe naked babies for signs of distress over the first few hours after birth, during the so-called transition or observation period. The “observation nursery” is now a thing of the past and has been replaced by the “intermediate care nursery” for infants with a minor degree of instability such as mild respiratory distress, irritability, jaundice, or risk for sepsis. Monitoring these infants with temperature probes as well as by means of vital signs has facilitated the provision of a TNE without needing a NICU admission. This device and the primitive delivery room heaters led to the development of the current radiant warmers now in common use in NICUs. They produce overhead heat in the infrared range distributed in a uniform fashion to the infant and controlled by an abdominal skin thermistor. The temperature

probe itself, not the skin temperature, controls heat output. Insensible water loss is slightly greater and exaggerated if humidity falls below 50%. Open access under the warmer is excellent and advantageous in the assessment and management of the seriously ill infant on admission.

Comparisons of the superiority of the incubator over the radiant warmer have shown no differences in outcome. Both methods are effective and safe and appropriate for the care of the extremely low birth weight newborn, with recognition of small differences in insensible water loss. The more recent development of a hybrid incubator allows the intermittent use of a vertically adjustable radiant heater as well as drop-down incubator walls to improve access. Advocates for its use suggest that the incidence of severe bronchopulmonary dysplasia may be lessened and that better fluid balance and growth velocity may be achieved (Kim, 2010). Further studies are needed.

Weaning to an Open Crib

The continuing need for an incubator is relevant to discharge planning and home care. Body weight attainment serves as a useful indicator as the infant approaches a weight of 1600 g. Infants weighing 1500 g transferred to an unheated open crib demonstrate satisfactory growth velocity and a stable temperature without other adverse effects (Berger et al., 2014). However, earlier transfer to an open crib does not necessarily relate to earlier discharge. Crib nursing of full-term infants requires a room temperature of at least 24°C, while infants of 1500 g should be in an environment of 26°C–28°C. The smaller infants should be fully dressed, including a head covering, and may require a room temperature of 30°C.

Skin-to-Skin Care

“Kangaroo mother care” was originally used as an effective way for mothers to keep their full-term babies warm while breastfeeding and subsequently as an alternative method of caring for low birth weight (LBW) babies in resource-limited countries. In these original versions, the infant is placed skin-to-skin in a vertical position between the mother’s breasts and under her clothes and is exclusively (or almost exclusively) breastfed. More recently, intermittent SSC, provided by the mother or father, has been introduced in resource-rich countries for babies requiring neonatal intensive care—even extremely premature infants and those on ventilators. Enhanced parental bonding, facilitation of breastfeeding, better sleep patterns, and procedural pain relief are some of its purported benefits. Several guidelines regarding SSC in the NICU have been published, but since it requires intensive staffing support, resources, and parent participation, development of individualized unit guidelines has been recommended (Baley and Committee on Fetus and Newborn, 2015).

Temperature regulation during SSC has been a concern for both care providers and parents and may limit its use. Karlsson et al. (2012) evaluated thermal balance in extremely preterm neonates before, during, and after SSC during the first week after birth. Neonates maintained normal body temperature, although transfer to and from the parent was associated with a drop in skin temperature, and insensible water loss through the skin was higher during SSC. The authors concluded that conduction of heat from parent to infant is sufficiently high to compensate for the increase in evaporative and convective heat loss. A metaanalysis reported a statistically (but not clinically) significant increase in body temperature and decrease in oxygen saturation in term and preterm

infants receiving SSC compared with incubator care, although this was more evident in lower-resource than in higher-resource settings, and in cold environments (Mori et al., 2010).

In a 2015 clinical report regarding SSC in the NICU, the Committee on Fetus and Newborn of the American Academy of Pediatrics recommended that NICU infants should be continuously monitored during SSC and that “any infant who requires careful temperature regulation or a high-humidity environment might have SSC delayed until he or she is more stable” (Baley and Committee on Fetus and Newborn, 2015).

Additional Considerations

Transport

Temperature instability during transport to a NICU remains a challenging problem particularly for extremely low birth weight neonates. Neonates born at less than 25 weeks’ gestation, even those delivered within a tertiary care center, are commonly noted to have a drop in core temperature within 12 hours of admission to a NICU (Costeloe et al., 2000). A review of several thousand LBW infants in the National Institute of Child Health and Human Development Neonatal Research Network who were admitted directly from the delivery room to the NICU revealed an association between lower admission temperature and lower birthweights as well as the need for immediate intubation. Admission temperature was inversely related to mortality (28% increase per 1°C decrease) and the incidence of late-onset sepsis (11% increase per 1°C decrease) (Laptook et al., 2007).

Interhospital transport, particularly for critically ill and/or VLBW neonates, increases the risk of thermal instability. Infants may be exposed to a cooler, draftier non-NICU environment at the referring hospital and in transfer to and from the transport incubator. Evaluation and stabilization efforts—often accompanied by the movement of multiple care providers and equipment—can also increase convective heat losses. Intubation equipment, vascular access instruments, cold inspired air, unheated intravenous solutions or medications, and cold hands may increase conductive heat losses. One level III referral NICU recently used transport risk index of physiologic stability (TRIPS) scores to evaluate the impact of transport on the physiologic stability of VLBW infants. It was found that more than half the transported infants demonstrated deterioration in their TRIPS score, primarily because of a decrease in temperature, and the likelihood increased with longer duration of transport. It was concluded that better temperature regulation during transport may decrease the risk of clinical deterioration in such infants (Arora et al., 2014).

As discussed previously, the use of occlusive plastic wraps and a hat is advocated while evaluation, resuscitation, and/or stabilization measures are occurring. However, additional warming methods are often needed and may be provided by a heated gel mattress and a radiant warmer. The urgency of cardiopulmonary stabilization and other life support measures may take priority over the many details of heat loss prevention, and development of standard temperature care protocols and team training in their use—for every neonatal transport—is recommended.

Hypothermia

Induced hypothermia by controlled cooling of the body or head for the treatment of neonatal encephalopathy is discussed in Chapter 62.

Once infants have a decrease in their core temperature, they have exceeded their ability to generate sufficient heat by increasing metabolism. How best and how quickly should rewarming occur to reach a core temperature of 36°C without increasing oxygen consumption or metabolism? Few data exist to support the optimal rate of rewarming. Current protocols favor a rapid return to a TNE with extra heat provided by radiant heat and a heated mattress or an incubator. A decrease in core temperature in VLBW infants, especially in the first hours of life, remains an important risk factor for increased morbidity and mortality. The World Health Organization, concerned that neonatal hypothermia is prevalent around the world as a contributor to inadequate newborn care, has developed a classification system to underscore the importance of intervention. Three levels are defined:

1. “Cold stress” or mild hypothermia: temperature 36.0°C–36.4°C
2. Moderate hypothermia: temperature 32.0°C–35.9°C
3. Severe hypothermia: temperature below 32°C

A retrospective study assessing these criteria found that approximately 56% of VLBW newborns were moderately hypothermic in the first few hours of life and had an associated adjusted risk factor for an increase in intracranial hemorrhage (odds ratio [OR] 1.3) and death (OR 1.5) (Miller, 2011). Therefore emphasis on the need for rewarming has been focused on the care of infants at risk of “moderate” hypothermia.

Rewarming involves setting a skin thermistor at a desired level of 37°C or 38°C, and under a radiant heat core temperature of 37°C can be achieved in 4 hours with a set point of 37°C or 2 hours with a set point of 38°C. Although there is minimal evidence for an increase in apnea or hypoglycemia, both should be monitored.

Hyperthermia

Overheating (core temperature above 37.3°C) can result in tachycardia, tachypnea, restlessness, and so-called heat stress. It is important to assess whether the cause is environmental or caused by infection such as sepsis. Measurement of the abdominal skin temperature and that of the foot or toe should normally reveal a difference of 2.0°C. As core temperature increases because of an

infection, vasoconstriction of the periphery will occur in an effort to support the body's effort to increase central temperature. Therefore a toe-to-abdominal skin temperature difference of greater than 2.5°C would indicate an infection rather than an environmental cause. However, it is unclear whether extremely immature infants are able to mount a vasomotor response. If the abdomen-to-toe temperature gap is less than 1°C or reversed, this indicates excess heat is being applied. Environmental temperature should be reduced by 0.5°C at intervals of about 30 minutes, with excess layers of clothing removed. Again, the abdomen-to-toe temperature gap in the extremely LBW infant may be unreliable because of impaired control of microvascular perfusion, and thus monitoring of other signs of overheating is more important.

Bathing

There is a tendency for all neonates, large and small, to be bathed soon after birth. In some cultures, customs and rituals associated with birth dictate the timing of naming, cord separation, first feed, and first bath, among other events. Early bathing is probably of limited value and can safely be delayed, but there is often a desire to rid the skin of its coating of vernix. The vernix is made up of a thick coat of mostly lipids, including triglycerides, free fatty acids, and cholesterol esters. Its function is not fully understood, but it probably provides barrier function, primarily for transepidermal water movement in utero, and may have a similar role after birth as well as providing mechanical protection. There is no evidence that it plays a role in thermal protection, but it may provide some benefit to the premature neonate.

There is recent evidence that one benefit of a vaginal delivery is the transfer of organisms in the maternal microbiome to the infant, leading to the suggestion that smearing infants born by cesarean delivery with vaginal secretions would be of benefit to establishing a microbiome pattern akin to that of the mother. Bathing would interfere with that goal. Bathing may also increase heat loss through evaporation. Therefore to minimize exposure it is recommended that newborns be bathed starting with the trunk and concluding with the head with its greater evaporative surface area, thus minimizing heat loss.

Summary

Body temperature homeostasis is but one element of the normal adaptation to extrauterine life for all newborns. Prevention of heat loss is especially important in reducing morbidity and mortality in premature newborns. Hypothermia in critically ill infants whether due to prematurity, respiratory distress, sepsis, asphyxia, congenital anomalies, or other abnormalities will result in increased energy expenditure and oxygen consumption. Protocols and guidelines have been developed for protective management applications based on clinical trials and physiologic rationale and are periodically revised by medical and technical staff. The use of sophisticated equipment requires constant monitoring of heat output and the neonates' core temperature with the goal of providing the appropriate thermal neutral environment. It is particularly important for care providers to understand the consequences of heat loss in fragile neonates.

Several challenges remain, particularly in the maintenance of body temperature of extremely LBW newborns in the delivery room, during transport to the NICU, and in the first few hours after birth. This is due in part to resuscitative and stabilization

efforts that may take priority over wrapping and other temperature control procedures. However, there is room for improvement in the coordinated and simultaneous approach to the prevention of unintended cooling without delaying or impeding necessary resuscitation and stabilization procedures. This should be emphasized within the current American Academy of Pediatrics Neonatal Resuscitation Program manual. There is a need for improvement in the standards for optimal humidification levels for incubators and radiant warmers as current assessment of nurseries indicate wide variations from below 50% up to 100%.

Future modifications of existing equipment will probably be directed at improving safety and efficacy in maintaining strict and accurate control of the appropriate thermal neutral environment. The use of noncontact infrared thermography to measure multiple skin sites simultaneously is being evaluated (Herman et al., 2013). Different areas of the skin may indicate temperature fluctuations under different conditions, such as movement from an incubator to SSC and back, effects of phototherapy, vasomotor instability, and sites of conductive heat loss. Detecting changes in the peripheral

perfusion index may provide a clue to early signs of the development of necrotizing enterocolitis. Infrared thermal imaging can provide minute-to-minute information from various sites and may be useful in studying the developmental changes in the neural control of temperature (central and peripheral receptors) with advancing gestational and postnatal age. It will require a handheld camera or video recorder for continuous monitoring.

The concept of substituting an individual laminar flow device over each infant has theoretical advantages over the existing incubator and radiant warmer (Perez et al., 2013). It would provide warmed convective and filtered air, an embedded humidifier,

microbial isolation, and open access without taking up any more space than an overhead warmer. Further development of such a device lies in the future; however, a very positive aspect is an apparent strong fidelity for providing excellent thermal and microbial protection as well as improved patient access.

Perhaps the larger and more important need for the future is to work toward reducing newborn morbidity and mortality in lower-income and middle-income countries. Improved temperature regulation may provide the stepping stone for introducing more advanced newborn care, as has occurred with the history of modern newborn care in the developed world.

Fluid, Electrolyte, and Acid–Base Balance

CLYDE J. WRIGHT, MICHAEL A. POSENCHEG, ISTVAN SERI,
AND JACQUELYN R. EVANS

KEY POINTS

- Many pathologic states in the neonate are associated with disruptions in normal body fluid, electrolyte, and acid–base balance, which at times may in themselves be life threatening.
- The maintenance of normal fluid, electrolyte, and acid–base balance is a cornerstone of appropriate management of the sick neonate

Fluid and Electrolyte Balance

Maintenance of fluid and electrolyte balance is essential for normal cell and organ function during intrauterine development and throughout extrauterine life. Pathologic conditions in the newborn often lead to disruption of the complex regulatory mechanisms maintaining homeostasis. Therefore a thorough understanding of the physiologic changes in the neonatal period and the provision of appropriate therapies based on the principles of developmental fluid and electrolyte physiology are among the cornerstones of modern neonatal intensive care.

Developmental Changes Affecting Fluid and Electrolyte Balance in the Fetus and Neonate

Developmental Changes in Body Composition and Fluid Compartments

Dynamic changes occur in body composition and fluid distribution during intrauterine life, labor and delivery, and the early postnatal period. Thereafter the rate of change in body composition and fluid distribution gradually decreases, with subtler changes occurring especially after the first year of age (Friis-Hansen, 1961).

Changes During Intrauterine Development

In early gestation, body composition is characterized by a high proportion of total body water (TBW) and a large extracellular compartment (Friis-Hansen, 1983; Brans, 1986). As gestation advances, rapid cellular growth, accretion of body solids, and fat deposition and developmental changes in the production of hormones regulating body water homeostasis result in gradual reductions in TBW content and extracellular fluid (ECF) volume, while the intracellular fluid compartment increases (Fig. 30.1)

(Friis-Hansen, 1983). In the 16-week-old fetus, TBW represents approximately 94% of total body weight; approximately two-thirds of the TBW is distributed in the extracellular compartment, and approximately one-third is distributed in the intracellular compartment. By term, TBW contributes only 75% of body weight, and approximately half of this volume is located in the intracellular compartment. Therefore premature newborns have excess TBW and a larger extracellular volume compared with their term counterparts, with most of the expanded extracellular volume being distributed in the interstitium (Bauer, 2011).

Changes During Labor and Delivery

Greater changes in TBW and its distribution occur during labor and delivery. Arterial blood pressure rises several days before delivery because of increases in plasma catecholamine, vasopressin, and cortisol levels and translocation of blood from the placenta into the fetus. This rise in arterial blood pressure, along with changes in the fetal hormonal milieu and an intrapartum hypoxia-induced increase in capillary permeability, results in a shift of fluid from the intravascular to the interstitial compartment and an associated approximately 25% reduction in circulating plasma volume in the human fetus during labor and delivery (Bauer, 2011). The postnatal increase in oxygenation and changes in vasoactive hormone production act to restore capillary membrane integrity and favor absorption of interstitial fluid into the intravascular compartment. The return of interstitial fluid into the bloodstream aids in maintaining intravascular volume during the first 24–48 hours postnatally, when oral fluid intake may be limited. However, prematurity, pathologic conditions, or both can disrupt this delicate process and interfere with the physiologic contraction of the ECF compartment in the immediate postnatal period.

In the fetus, body composition and fluid balance depend on the electrolyte and water exchange between the mother, fetus, and amniotic space (Brace, 1986). Antenatal events can have significant effects on postnatal fluid balance. Maternal indomethacin treatment or excessive administration of intravenous (IV) fluids during labor can result in neonatal hyponatremia with expanded extracellular water content (Rojas et al., 1984; vd Heijden et al., 1988). Placental insufficiency or maternal diuretic therapy can impair fetal extracellular volume, urine output, and amniotic fluid volume (Van Otterlo et al., 1977).

• **Fig. 30.1** Total body water content and its distribution between the extracellular fluid and intracellular fluid compartments in the human fetus, newborn, and infant from conception until 9 months of age. ECF, Extracellular fluid; ICF, intracellular fluid; TBW, total body water. (The data represent average values from Friis-Hansen B. Body water compartments in children: changes during growth and related changes in body composition. *Pediatrics* 1961;28:169–181.)

Effect of Timing of Cord Clamping

The timing of cord clamping after delivery is another important factor significantly affecting total circulating blood volume and extracellular volume in the neonate. Immediate cord clamping does not allow placental transfusion and negatively influences hemodynamic transition, especially in the preterm neonates (Hooper et al., 2015a). However, if the cord clamping is delayed, up to 25–50 mL of blood per kilogram is transfused into the neonate, representing an approximate 25%–50% increase in the total blood volume (Yao and Lind, 1974; Linderkamp, 1982). In a metaanalysis of term neonates, delayed cord clamping for at least 30 seconds was associated with increased iron stores and higher birth weight but with a higher need for phototherapy (McDonald et al., 2013). In a metaanalysis in preterm neonates, delayed cord clamping was associated with significantly decreased intraventricular hemorrhage (IVH), necrotizing enterocolitis, and need for inotropic support and blood transfusion (Rabe et al., 2012). Although concern about delaying neonatal resuscitation has been cited as a reason for not delaying cord clamping (Jelin et al., 2014), this concern may be decreasing (Katheria et al., 2016). Of note is that, according to recent animal data (Hooper et al., 2015b) and earlier observations in term neonates (Philip and Teng, 1977), the establishment of an appropriate functional residual capacity, usually with the onset of spontaneous respiration at birth, is the most relevant factor in determining the volume and rapidity of placental transfusion. Accordingly, neonates who do not establish effective respirations and who require resuscitation at birth may be at additional risk of lower circulating blood volumes. Although further follow-up is needed to understand whether increased blood volume at birth is associated with improved long-term outcomes, on the basis of current data, the American College of Obstetricians and Gynecologists recommends delaying cord clamping for 30–60 seconds after birth in preterm but not term neonates, whereas the World Health Organization recommends delaying cord clamping for 30–60 seconds in all neonates (World Health Organization, 2014).

Changes in the Postnatal Period

In the first few days and weeks after birth, the TBW content and distribution are affected by gestational and postnatal ages, pathologic conditions, the immediate environment (temperature, humidity), and the type of nutrition (enteral vs. parenteral). Normally, in the first few days after birth, an increase in capillary membrane integrity favors absorption of the interstitial fluid into the intravascular compartment (Modi, 2004). The ensuing rise in circulating blood volume stimulates the release of atrial natriuretic peptide (ANP) from the heart, which in turn enhances renal sodium and water excretion (Sagnella and MacGregor, 1984), resulting in an abrupt decrease in TBW and attendant weight loss. Although it is generally accepted that this postnatal weight loss is primarily due to the contraction of the expanded ECF compartment (Cheek et al., 1961), some water loss from the intracellular compartment can also occur, particularly in infants with extremely low birth weight (ELBW) and increased transepidermal water losses (TEWLs) (Costarino and Baumgart, 1991; Sedin, 1995; Modi, 2004).

Healthy term newborns lose approximately 10% of their birth weight during the first 4–7 days of age (Bauer et al., 2011), and thereafter they establish a pattern of steady weight gain. Because preterm neonates have an increased TBW content and extracellular volume, they lose approximately 10%–15% of their birth weight during this period (Shaffer and Meade, 1989; Bauer, 2011) and, depending on the degree of prematurity and associated pathologic conditions, these neonates only regain their birth weight by 10–20 days after birth (Fig. 30.2). Neonates who have intrauterine growth retardation have a smaller initial weight loss and more rapidly regain their birth weight than their normally grown counterparts, whether term or preterm (Bauer et al., 1993). Although the mechanisms for these differences have not been well studied, they appear to be associated with less diuresis in the infant with intrauterine growth retardation (Bauer et al., 1993; Méio et al., 2008).

It is important in management of the neonate that the appropriate weight loss be anticipated and facilitated, if necessary, as lack of the early postnatal weight loss has been associated with higher rates of persistency of the patent ductus arteriosus (PDA), bronchopulmonary dysplasia (BPD), and necrotizing enterocolitis in low birth weight infants (Bell et al., 1979; Stonestreet et al., 1983; Saalmüller et al., 1994; Oh et al., 2005; Bell et al., 2014).

Physiology of the Regulation of Body Composition and Fluid Compartments

Although human cells have the ability to adjust their intracellular composition, extracellular volume and osmolality impact intracellular conditions, and if the changes are too dramatic, they may go beyond the cells' capacity to appropriately maintain the intracellular milieu. Therefore monitoring and active regulation of extracellular volume and osmolality are necessary in sick infants and those born prematurely.

Regulation of the Intracellular Solute and Water Compartment

The major intracellular solutes are the proteins necessary for cell function, the organic phosphates associated with cellular energy production and storage, and the equivalent cations balancing the phosphate and protein anions (MacKnight and Leaf, 1977). Potassium is the major intracellular cation, and sodium is the major extracellular cation. The energy derived from the concentration differences for sodium and potassium between the intracellular and extracellular compartments is used for cellular work. Because changes in osmolality of the extracellular compartment are reflected

• **Fig. 30.2** Postnatal changes in body weight (expressed as a percentage of birth weight), extracellular fluid volume (estimated by the bromide dilution method), and sodium balance (defined as the difference between sodium intake and urinary sodium excretion). (From Shaffer SG, Weismann DN. Fluid requirements in the preterm infant. *Clin Perinatol*. 1992;19:233–250.)

as net movements of water into or out of the cell, regulation of ECF osmolality ultimately controls the intracellular compartment (MacKnight and Leaf, 1977). This physiologic principle must be kept in mind by the neonatologist managing sick term and preterm neonates with disturbances of sodium homeostasis. Rapid changes in serum sodium concentration and thus in extracellular osmolality directly affect the osmolality and size of the intracellular compartment and can lead to irreversible cell damage, especially in the central nervous system (CNS). Hyponatremia in the neonatal period has been associated with adverse long-term outcomes, especially in preterm neonates, while hypernatremia has been associated with short-term morbidities, including seizures and thrombosis (Morris-Jones et al., 1967; Escobar et al., 2007; Unal et al., 2008; Baraton et al., 2009; Moritz et al., 2009). These associations underscore

• **Fig. 30.3** Filtration and reabsorption of fluid along the capillary under physiologic conditions. A, Arterial; P_C , capillary hydrostatic pressure; P_T , tissue/interstitial hydrostatic pressure; V, venous; π_P , plasma oncotic pressure; π_T , tissue/interstitial oncotic pressure.

the importance of fluid and electrolyte homeostasis in the neonatal period.

Regulation of the Intracellular–Extracellular Interface: the Interstitial Compartment

In the healthy term neonate, hydrostatic (P_C , capillary hydrostatic pressure; P_T , tissue/interstitial hydrostatic pressure), and oncotic (π_P , plasma oncotic pressure; π_T , tissue/interstitial oncotic pressure) pressures are well balanced, with both being approximately half those in the adult (Sola and Gregory, 1981). In normal physiologic conditions, movement of fluid across the capillary is determined by the direction of the net driving pressure ($[P_C - P_T] - [\pi_P - \pi_T]$) and the water and protein permeability characteristics of the capillary wall (Fig. 30.3). At the arterial end of the capillary, intracapillary hydrostatic pressure (P_C) is high and plasma oncotic pressure (π_P) is relatively low, resulting in a net movement of fluid out of the capillary. As filtration of relatively protein-poor fluid continues along the capillary, plasma oncotic pressure rises and intracapillary hydrostatic pressure drops; therefore on the venous side, fluid moves from the interstitium into the capillary, so much of the filtered fluid is reabsorbed at the end of the capillary bed. The fluid remaining in the interstitium (arterial–venous side of the capillary) is drained by the lymphatic system. Interstitial hydrostatic (P_T) and oncotic (π_T) pressures remain virtually unchanged along the capillary bed. However, pathologic conditions readily disturb the delicate balance between the hydrostatic and oncotic forces, leading to an expansion of the interstitial compartment at the expense of the intravascular compartment. The increased interstitial fluid volume (edema) then further affects tissue perfusion by altering the normal function of the extracellular–intracellular interface. Box 30.1 summarizes the mechanisms for conditions resulting in interstitial edema formation in the neonate. There are also some important developmentally regulated differences between the newborn and the adult relating to the pathogenesis of edema formation. Capillary permeability to proteins is increased during the early stages of development (Gold and Brace, 1988; Bauer, 2011). Because neonatal capillary permeability is further increased under pathologic conditions (see Box 30.1), protein concentration in the interstitial compartment may approach that of the intravascular space, favoring further intravascular volume depletion and interstitial volume expansion. However, although the findings of most (Bignall et al., 1989; So et al., 1997; Oca et al., 2003) but not all (Lynch et al., 2008) clinical studies suggest that 0.9% saline administration for suspected hypovolemia is associated with less fluid retention and similar

• BOX 30.1 Mechanisms for Conditions Causing Interstitial Edema in the Neonate

Conditions Favoring Fluid Accumulation in the Interstitial Space by Causing a Disequilibrium Between Filtration and Reabsorption of Fluid by the Capillaries

Increased hydrostatic pressure
 Elevated capillary hydrostatic pressure
 Increased cardiac output
 Venous obstruction
 Decreased tissue hydrostatic pressure
 Conditions associated with changes in the properties of the interstitial gel (edematous states, effects of hormones including prolactin)
 Decreased oncotic pressure gradient
 Decreased capillary oncotic pressure
 Prematurity, hyaline membrane disease
 Malnutrition, liver dysfunction
 Nephrotic syndrome
 Increased interstitial oncotic pressure is usually the result of increased capillary permeability.
 Elevation of the filtration coefficient
 Increased capillary permeability
 Organs with large-pore capillary endothelium (liver, spleen)
 State of maturity (preterm infants > term newborns > adults)
 Production of proinflammatory cytokines (sepsis, anaphylaxis, hypoxic tissue injury, tissue ischemia, ischemia–reperfusion, soft tissue trauma, extracorporeal membrane oxygenation)
 Increased capillary surface area
 Vasodilation

Conditions Associated With Decreased Lymphatic Drainage

Decreased muscle movement
 Neuromuscular blockade and/or heavy sedation
 Central and/or peripheral nervous system disease
 Obstruction of lymphatic flow
 Increased central venous pressure
 Scar tissue formation (bronchopulmonary dysplasia)
 Mechanical obstruction (dressings, high mean airway pressure in mechanically ventilated newborns)

improvements in the cardiovascular status compared with 4.5% or 5% albumin infusion, the topic remains controversial.

Even in the presence of hypoalbuminemia, when sick neonates are treated with frequent albumin boluses, much of the infused albumin rapidly leaks into the interstitium. This creates a vicious cycle of intravascular volume depletion and edema formation, resulting in vasoconstriction and disturbances in tissue perfusion and cellular function, exacerbating impairments in the regulation of extracellular volume distribution. If the cycle is not interrupted, anasarca will develop, which is usually associated with an extremely poor prognosis. In summary, the sick neonate has limited capacity to maintain appropriate intravascular volume and to regulate the volume and composition of the interstitium, and thus high vigilance is required by the caretaker in appropriately managing intravascular volume, including avoiding routine use of albumin in the critically ill neonate (Uhing, 2004).

Regulation of the Extracellular Solute and Water Compartment

The osmolality of the extracellular compartment is tightly maintained within 2% of the osmolar set point, which lies between 275 and 290 milliosmole (mOsm) (Robertson and Berl, 1986). Blood pressure and serum sodium concentration (i.e., the main

contributor to osmolality under homeostatic conditions) are monitored by baroreceptors and osmoreceptors respectively. The effector limb of the regulatory system consists of the heart, vascular bed, kidneys, and intake of fluid in response to thirst. The inability of critically ill term and preterm neonates to maintain fluid balance by responding to thirst places increased importance on caregiver management of fluid administration. By regulating the function of the effector organs, several hormones play a role in the control of the extracellular compartment, including the renin–angiotensin–aldosterone system, vasopressin, ANP, brain (B-type) natriuretic peptide (BNP), bradykinin, prostaglandins, and catecholamines. Effective regulation of the extracellular compartment and intravascular volume also depends on intact cardiovascular function and capillary endothelium integrity (Robertson and Berl, 1986). For example, under physiologic conditions, an increase in the extracellular volume is reflected by an increase in the circulating plasma volume, leading to increased blood pressure and renal blood flow. The ensuing increase in glomerular filtration and urine output returns the extracellular volume to normal. In critically ill neonates, however, the capillary leak and reduced myocardial responsiveness resulting from immaturity and underlying pathologic conditions limit the increase in the circulating blood volume when extracellular volume expands. Thus especially in sick preterm neonates, blood pressure may rise only transiently (Lundström et al., 2000), and renal blood flow may remain low after volume boluses as fluid rapidly leaks into the interstitium. Inappropriate central regulation of vascular tone results in vasodilatation, further decreasing effective circulating blood volume and compromising tissue perfusion; this leads to impaired gas exchange in the lungs, resulting in hypoxia with further increases in capillary leak. Unless it is interrupted by appropriate therapeutic measures, a vicious cycle with further deterioration readily occurs in the sick neonate.

Maturation of Organs Regulating Body Composition and Fluid Compartments

The heart, kidneys, skin, and endocrine system play the most important roles in the regulation of ECF (and thus intracellular fluid) and electrolyte balance in the neonate. Immaturity of these organ systems, especially in infants with very low birth weight (VLBW), results in a compromised regulatory capacity, which must be noted when one is estimating daily fluid and electrolyte requirements in these patients.

Maturation of the Cardiovascular System

There is a direct relationship between gestational maturity and the ability of the neonatal heart to respond to acute volume loading (Baylen et al., 1986). The blunted Starling response of the immature myocardium results from its lower content of contractile elements and incomplete sympathetic innervations (Mahony, 1995). Because central vasoregulation and endothelial integrity are also developmentally regulated (Gold and Brace, 1988; Bauer, 2011), an appropriate effective intravascular volume is seldom maintained in the critically ill preterm neonate. Since regulation of the extracellular volume requires the maintenance of an adequate effective circulating blood volume, the immaturity of the cardiovascular system contributes to the limited capacity of sick preterm neonates to effectively regulate the total volume of their extracellular compartment.

Maturation of Renal Function

The kidney has a crucial role in the physiologic control of fluid and electrolyte balance. It regulates extracellular volume and

• **Fig. 30.4** Transepidermal water loss in relation to gestational age during the first 28 postnatal days in newborns who are appropriate for their gestational age. There is an exponential relationship between transepidermal water loss and gestational age, the water loss being higher in preterm newborns than in term newborns. Transepidermal water loss is also significantly affected by postnatal age, especially in the immature preterm newborn. The measurements were performed at ambient air humidity of 50% and with the newborns calm and quiet. (From Hammarlund K, Sedin G, Stromberg B. Transepidermal water loss in newborn infants. VIII: relation to gestational age and post-natal age in appropriate and small for gestational age infants. *Acta Paediatr Scand.* 1983;72:721–728.)

osmolality through the selective reabsorption of sodium and water respectively. Immaturity of renal function renders preterm neonates susceptible to excessive sodium and bicarbonate losses (Modi, 2004; Brewer, 2011). In addition, the inability of the preterm neonate to respond promptly to a sodium or volume load results in a tendency toward extracellular volume expansion with edema formation. Because prenatal steroid administration accelerates maturation of renal function (van den Anker et al., 1994), preterm neonates exposed to steroids in utero have a better capacity to regulate their postnatal ECF contractions. During the first few weeks postnatally, hemodynamically stable but extremely immature infants produce dilute urine and may develop polyuria because of their renal tubular immaturity. As tubular functions mature, their concentrating capacity gradually increases from the second week to the fourth week of postnatal life. However, it takes years for the developing kidney to reach the concentrating capacity of the adult kidney (Linshaw, 2011).

Maturation of the Skin

Although the epidermis of term neonates is well developed and cornified, in extremely immature neonates it consists of only two or three cell layers (Chu and Loomis, 2011). The absence of an effective barrier to the diffusion of water increases TEWL in the immature neonate. TEWL through immature skin can result in early postnatal hypertonic dehydration, with rapid changes in intracellular volume and osmolality. In many organs, especially the brain, these abrupt changes can result in cellular dysfunction and ultimately cell death. Gestational age, postnatal age, the pattern of intrauterine growth, and environmental factors (e.g., humidity and temperature) affect transepidermal free water loss (Fig. 30.4).

Postnatal skin cornification occurs rapidly, but full maturation of the epidermis does not occur until 2–3 weeks of age (Cartledge, 2000). Chronic intrauterine stress (Hammarlund et al., 1983) and prenatal steroid treatment (Aszterbaum et al., 1993) also enhance maturation of the skin.

Maturation of End-Organ Responsiveness to Hormones Involved in the Regulation of Fluid and Electrolyte Balance

Several hormones directly regulate the volume and composition of the extracellular compartment by altering renal sodium and water excretion and by inducing changes in systemic vascular resistance and myocardial contractility. These include the renin–angiotensin–aldosterone system, vasopressin, ANP, and BNP. Other hormones, including the prostaglandins, bradykinin, and prolactin, modulate the actions of many of the regulatory hormones.

Renin–Angiotensin–Aldosterone System. Decreases in renal capillary blood flow stimulate renin secretion from the juxtaglomerular cells of the kidney, which in turn catalyzes the conversion of angiotensinogen to angiotensin I. Angiotensin-converting enzyme hydrolyzes angiotensin I to angiotensin II, which can then bind to the cell membrane-bound receptors AT_1 and AT_2 (Sequeira et al., 2011). Angiotensin induces vasoconstriction, increased tubular sodium and water reabsorption, and the release of aldosterone (Sequeira et al., 2011). Aldosterone increases potassium secretion and further enhances sodium reabsorption in the distal tubule; therefore the primary function of this system is to protect the volume of the extracellular compartment and maintain adequate tissue perfusion (Bailie, 1992). However, its effectiveness in the neonate is somewhat limited by the decreased responsiveness of the immature kidney to the sodium-retaining and water-retaining

effects of these hormones (Sulyok et al., 1985; Feld et al., 2011). Vasodilatory and natriuretic prostaglandins generated in the kidney (Gleason, 1987) are the main counterregulatory hormones balancing the renal actions of the renin–angiotensin–aldosterone system. Therefore when prostaglandin production is inhibited by indomethacin, the unopposed vasoconstrictive and sodium-retentive actions of the activated renin–angiotensin–aldosterone system contribute to the development of the drug-induced renal failure in the preterm neonate (Gleason, 1987; Seri, 1995; Seri et al., 2002).

Vasopressin. Vasopressin (antidiuretic hormone) regulates the osmolality of the extracellular compartment and directly effects vascular tone through the V_{1a} and V_2 receptors. Vasopressin selectively raises free water reabsorption through the upregulation of aquaporin-2 water channels in the collecting duct, resulting in blood pressure elevation (Elliot et al., 1996; Linshaw 2011). Although it appears that the developing kidney is less sensitive to circulating vasopressin, plasma levels of vasopressin are markedly elevated in the neonate, especially after vaginal delivery, and its cardiovascular actions facilitate neonatal adaptation (Pohjavuori et al., 1985; Linshaw, 2011). The high vasopressin levels are in part also responsible for the diminished urine output of the healthy term neonate during the first day after birth. Under certain pathologic conditions, the dysregulated release of, or the end-organ unresponsiveness to, vasopressin significantly affects renal and cardiovascular functions and electrolyte and fluid status in the sick preterm and term neonate (Svenningsen et al., 1974). In the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), an uncontrolled release of vasopressin occurs in sick preterm and term neonates, with resulting water retention, hyponatremia, and oliguria. In the syndrome of diabetes insipidus, the lack of pituitary production of vasopressin or renal unresponsiveness to vasopressin results in polyuria and hypernatremia.

Atrial Natriuretic Peptide. Via its direct vasodilatory and renal natriuretic actions, the hormone ANP regulates the volume of the extracellular compartment in the fetus and neonate in a fashion opposite to that of the renin–angiotensin–aldosterone system (Seymour, 1985; Needleman et al., 1986; Solhaug and Jose, 2011). ANP has a direct inhibitory effect on renin production and aldosterone release (Christensen, 1993).

The stretch of the atrial wall caused by an increase in the circulating blood volume is the most potent stimulus for ANP release. Plasma levels are high in the fetus (Claycomb, 1988) and along with BNP, ANP likely plays a role in cardiac development (Das et al., 2009). There are a few specific conditions in which the actions of ANP are directly relevant for the neonatologist. For example, the hormone is involved in the regulation of both the fluid shifts during labor (Bauer, 2011) and the extracellular volume contraction during postnatal transition (Kojima et al., 1987; Tulassay et al., 1987; Rozycki and Baumgart, 1991; Ronconi et al., 1995). Furthermore, the oliguric effects of positive end-expiratory pressure ventilation are due in part to a decrease in ANP secretion (Christensen, 1993) along with the enhanced release of vasopressin (El-Dahr and Chevalier, 1990).

Brain (or B-Type) Natriuretic Peptide. BNP is released from the ventricular myocardium in response to increases in wall tension. Similarly to ANP, BNP causes natriuresis, diuresis, and vasodilatation, while inhibiting the renin–angiotensin–aldosterone system (Kojima et al., 1989; Gemelli et al., 1991; Holmes et al., 1993). Compared with ANP, BNP and the inactive N-terminal fragment of BNP (NT-proBNP) demonstrate longer half-lives and thus may be more useful clinical biomarkers as their levels are relatively more

stable over time (Vijlbrieff, 2012). NT-proBNP is renally excreted, and renal function should be considered when one is interpreting levels (Breuer, 2007).

BNP levels increase rapidly after birth, with the levels by the end of the first day up to 20-fold higher than those at birth (Yoshiyoshi et al., 1995; Mir et al., 2003), and they correlate with the downward trend in pulmonary arterial pressure, diuresis, and renal maturation in the days after birth, unlike ANP levels (Ikemoto et al., 1996). By causing vasodilatation and diuresis, high levels of BNP play a critical role in the hemodynamic transition of the fetus. BNP levels continue to fall during the first week after birth (Koch et al., 2003; Mir et al., 2003). The usefulness of measuring BNP levels is limited by the variability of levels in the first few days after birth as well as the variety of assays available to measure BNP levels. Its utility may ultimately lie in repeated measurements in the same patient over time with the same assay in order to follow trends.

Prostaglandins. Prostaglandins have a well-documented, counterregulatory role for the renal vascular and tubular effects of renin–angiotensin–aldosterone and vasopressin (Bonvalet et al., 1987). The inhibition of prostaglandin synthesis by indomethacin results in clinically important and sometimes detrimental renal vascular and tubular effects in the preterm neonate (Mercanti et al., 2009). Importantly, ibuprofen demonstrates fewer side effects than indomethacin on renal and mesenteric blood flow (Mercanti et al., 2009). How prostaglandins modulate the effects of the other regulatory hormones of neonatal fluid and electrolyte homeostasis is less well studied.

Prolactin. Prolactin plays a permissive role in the regulation of fetal and neonatal water homeostasis (Coulter, 1983; Pullano et al., 1989). High fetal plasma prolactin levels contribute to the increased tissue water content of the fetus. Postnatal prolactin levels remain high in the preterm neonate until approximately the 40th postconceptional week (Perlman et al., 1978). Low levels have been associated with increased risk of developing respiratory distress syndrome (RDS) (Gluckman et al., 1978; Hauth et al., 1978; Smith et al., 1980).

Management of Fluid and Electrolyte Homeostasis

General Principles of Fluid and Electrolyte Management

Fluid and electrolyte management is the cornerstone of neonatal intensive care, and appropriate management requires an understanding of the previously outlined physiologic principles and careful monitoring of key clinical data. Requirements vary substantially from infant to infant and in the same infant over time; therefore fluid prescription must be individualized and frequently reassessed. The primary goals are to maintain the appropriate ECF volume, ECF and intracellular fluid osmolality, and ionic concentrations.

Assessment of Fluid and Electrolyte Status

Maternal conditions during pregnancy, drugs and fluids administered to the mother during labor and delivery, and specific fetal and neonatal conditions all affect early fluid and electrolyte balance. Excessive administration of free water or oxytocin use in the mother can result in hyponatremia in the neonate. Maternal therapy with indomethacin, angiotensin-converting enzyme inhibitors, furosemide, and aminoglycosides can all adversely affect neonatal renal function. A newborn's history of oligohydramnios or birth asphyxia may also alert the clinician to the possibility of abnormal renal function. In young neonates, altered skin turgor, sunken anterior

fontanel, and dry mucous membrane are not sensitive indicators of dehydration, but tachycardia, hypotension, metabolic acidosis, and oliguria may be seen when intravascular volume is moderately to severely affected. In addition, edema usually occurs early when there is volume overload or illness. Serial measurements of body weight, intake and output, and serum electrolyte levels will usually provide the most precise and accurate information regarding overall fluid status.

Normally, both term and preterm neonates will void within the first 24 hours after birth (Clark, 1977). In most neonates without hemodynamic compromise, urine output increases from 1–2 mL/kg per hour on the first postnatal day to 3–5 mL/kg per hour by the third to fifth postnatal day and is associated with a weight loss of 5%–10% in term infants and 10%–15% in preterm neonates (Bidiwala et al., 1988). Frequently, onset of diuresis heralds resolution of RDS (Engle et al., 1983). In critically ill newborns and in situations of altered homeostasis, additional clinical data that may help in diagnosis and management include blood urea nitrogen (BUN) levels, serum and urine osmolality or specific gravity, and urine electrolyte and serum bicarbonate levels, along with close monitoring of blood pressure and heart rate. The frequency of monitoring depends on the extent of immaturity, the underlying pathologic condition, and the severity of the fluid and electrolyte disturbance.

Water Homeostasis and Management

Water Losses

Free water loss can be categorized as either insensible (skin and respiratory track) or sensible (urine and feces). Urine output is the most important source of sensible water loss. Extremely preterm neonates without systemic hypotension or renal failure usually lose 30–40 mL of water per kilogram per day in the urine on the first postnatal day and approximately 120 mL/kg per day by the third day. In stable, more mature preterm neonates born after 28 weeks' gestation, urinary water loss is approximately 90 mL/kg per day on the first postnatal day and 150 mL/kg per day by the third day (Coulthard and Hey, 1985). Because of their renal immaturity, preterm neonates have a tendency to produce dilute urine, thereby increasing their obligatory free water losses. In term neonates, urinary water loss is considerably less, approximating 40–60 mL/kg per day by the third day.

Normal water losses in the stool are less significant, amounting to approximately 10 mL/kg per day in term neonates and 7 mL/kg per day in preterm neonates during the first postnatal week (Sedin, 1995). Water losses in the stool increase thereafter and are influenced by the type of feeding and the frequency of stooling, which is higher in breastfed neonates.

In the preterm neonate, consideration of daily insensible water losses (IWLs) through the skin is critical (see Fig. 30.4). During the first few postnatal days, in a nonhumidified environment, TEWLs may be 15-fold higher in extremely premature neonates born at 23–26 weeks' gestation than in term neonates (Sedin, 1995). Although the skin matures rapidly after birth, even in extremely immature neonates, insensible losses are still somewhat higher at the end of the first month than in the term counterparts. Prenatal steroid exposure is associated with substantially less IWL in preterm neonates (Aszterbaum et al., 1993; Sedin, 1995; Omar et al., 1999).

Appropriate management of the neonate's immediate environment most effectively counteracts the high degree of IWL through immature skin. Among environmental factors, ambient humidity has the greatest effect on TEWL. In extremely immature neonates,

a rise in the ambient humidity in the incubator from 20%–80% decreases the TEWL by approximately 75% (Sedin, 1995). However, the use of an open radiant warmer more than doubles TEWLs (Flenady and Woodgate, 2003), and it is now standard of care to maintain extremely immature neonates in humidified incubators. Other factors that increase transepidermal IWL include phototherapy, especially when the neonate is nursed under low humidity, activity, airflow, elevated body, and environmental temperature as well as skin breakdown and skin or mucosal defects (e.g., gastrochisis, epidermolysis bullosa).

IWLs from the respiratory tract depend mainly on the temperature and humidity of the inspired gas mixture and on the respiratory rate, tidal volume, and dead space ventilation. In a healthy term newborn, the water loss through the respiratory tract is approximately half the total IWL if the ambient air temperature is 32.5°C and the humidity is 50% (Sedin, 1995). However, in neonates undergoing mechanical ventilation, there will be no IWL through the respiratory tract if the ventilator gas mixture is humidified at body temperature.

Extraordinary water losses are also seen in the neonate requiring intensive care. The most commonly encountered extraordinary losses occur when a nasogastric tube is placed under continuous suction (discussed in Surgical Conditions). Large losses may also occur in association with phlebotomy, chest tubes, surgical drains, ostomies, and fistulas as well as with emesis or diarrhea.

Management of Water Requirements

When managing the fluid status of the neonate, the clinician must consider fluid requirement dictated by three broad categories. First, any existing deficits or surpluses must be estimated. Secondly, ongoing maintenance needs to replace usual sensible and insensible losses, and support growth must be calculated. Finally, additional needs as a result of extraordinary losses should be anticipated. Importantly, while administered together, the composition of each of these fluids is unique and must be considered individually. For example, fluids given to replace ongoing losses from a chest tube or ostomy will require a different electrolyte composition than simple maintenance fluids to maintain hydration, and these will differ again from fluids given to support growth. The neonate's prenatal history, birth weight, gestational age, and need for mechanical ventilation and the environment in which the neonate is to be cared for should be considered when initial fluid and electrolyte needs are being determined. Frequent reevaluations are necessary. The most useful parameter for monitoring fluid balance is the weight of the baby, as rapid changes in weight will reflect changes in water balance. Serial weights can be used to estimate the IWL with use of the following formulas:

$$\text{IWL} = \text{Fluid Intake} - \text{Urine Output} + \text{Weight Loss}$$

or

$$\text{IWL} = \text{Fluid Intake} - \text{Urine Output} - \text{Weight Gain.}$$

It is reasonable to initiate fluid volume on the basis of the sum of an allowance for sensible water loss of 30–60 mL/kg per day and the estimated IWL. Fig. 30.4 shows usual IWL ranges by gestational and postnatal age. Factors previously outlined that predictably affect IWL should be considered when fluids are being prescribed. Prevention of excessive IWL rather than replacement of increased IWL is associated with fewer complications in the preterm neonate and can usually be achieved by modification of the neonate's environment. See Table 30.1 for usual maintenance fluid administration based on birth weight. These numbers are guidelines for initial

TABLE 30.1 Estimated Maintenance Fluid Requirements

| Birth weight (g) | DAILY FLUID REQUIREMENTS (mL/kg) | | | |
|------------------|----------------------------------|---------|----------|---------|
| | Day 1 | Day 2 | Days 3–6 | Day 7+ |
| <750 | 100–140 | 120–160 | 140–200 | 140–160 |
| 750–1000 | 100–120 | 100–140 | 130–180 | 140–160 |
| 1000–1500 | 80–100 | 100–120 | 120–160 | 150 |
| >1500 | 60–80 | 80–120 | 120–160 | 150 |

management only; the approach must subsequently be individualized on the basis of laboratory values and other clinical data.

It is important to remember that the TBW excess and extracellular volume expansion of preterm neonates imply that their negative water and sodium balance during the first 5–10 postnatal days (see Fig. 30.2; Shaffer and Meade, 1989) represents an appropriate adaptation to extrauterine life and should not be compensated for by increased fluid administration and sodium supplementation. If this principle is not followed, and a positive fluid balance (i.e., weight gain) is achieved during the transitional period, preterm neonates have been shown to be at higher risk of a more severe course of RDS (Shaffer and Weismann, 1992) and a higher incidence of PDA (Bell et al., 1980), congestive heart failure (Bell et al., 1980), pulmonary edema (Shaffer and Weismann, 1992), necrotizing enterocolitis (Bell et al., 1979), and BPD (Van Marter et al., 1990; Oh et al., 2005). However, most of the published studies on outcomes related to fluid balance were performed in the presurfactant era and before the widespread use of corticosteroids prenatally.

Infants with ELBW and others with anticipated fluid problems should be weighed daily or twice daily. Serum sodium levels should be measured every 4–6 hours until they have stabilized, usually by 3–4 days after birth, and urine output should be recorded and reviewed every 6–8 hours. In ELBW infants, electrolyte levels should be checked by 12 hours postnatally to help guide fluid management. Once data are available, fluids should be increased if weight loss is greater than 1%–2% per day in term neonates and 2%–3% per day in preterm neonates, if urine output is inappropriately low, if urine specific gravity is rising, or if serum sodium concentration is rising. Overall, expected and appropriate weight loss during the first week postnatally is up to 10% in term neonates and up to 15% in preterm neonates. Conversely, fluids should be decreased if weight is not falling appropriately and serum sodium concentration is decreasing. The goal is to reach 140–160 mL of fluids per kilogram per day by 7–10 days to allow adequate caloric intake.

Treatment of Fluid Overload

Fluid overload commonly occurs in sick neonates, often because of the use of fluid bolus administration for hypotension. The diagnosis is based on weight gain, edema, and often hyponatremia. Overhydration can sometimes be prevented by the use of blood transfusions or dopamine instead of colloid or crystalloid, if appropriate, for blood pressure support. In addition to reducing the need for volume boluses, dopamine may facilitate the process of extracellular volume contraction via its renal and hormonal effects (Seri, 1995). Once overhydration has occurred, management

is usually effected by 10%–20% decrements of total daily fluid intake and with careful monitoring of clinical and laboratory signs to ensure maintenance of adequate intravascular volume as well as normal glucose and electrolyte status while the ECF contraction occurs. While administration of albumin followed by a diuretic (e.g., furosemide) is frequently practiced in an attempt to mobilize interstitial fluid, there is little evidence to support this practice, and it may be counterproductive because of albumin leaking into the interstitial space (Uhing, 2004).

Treatment of Dehydration

Dehydration in the neonate may be suspected on the basis of history or clinical signs and confirmed by laboratory studies. One may estimate the total water deficit by using weight changes, calculating total inputs and outputs, and following serial sodium levels. Appropriate treatment requires consideration of sodium status. For additional details of fluid correction and sodium management, see the discussion in Treatment of Hyponatremia.

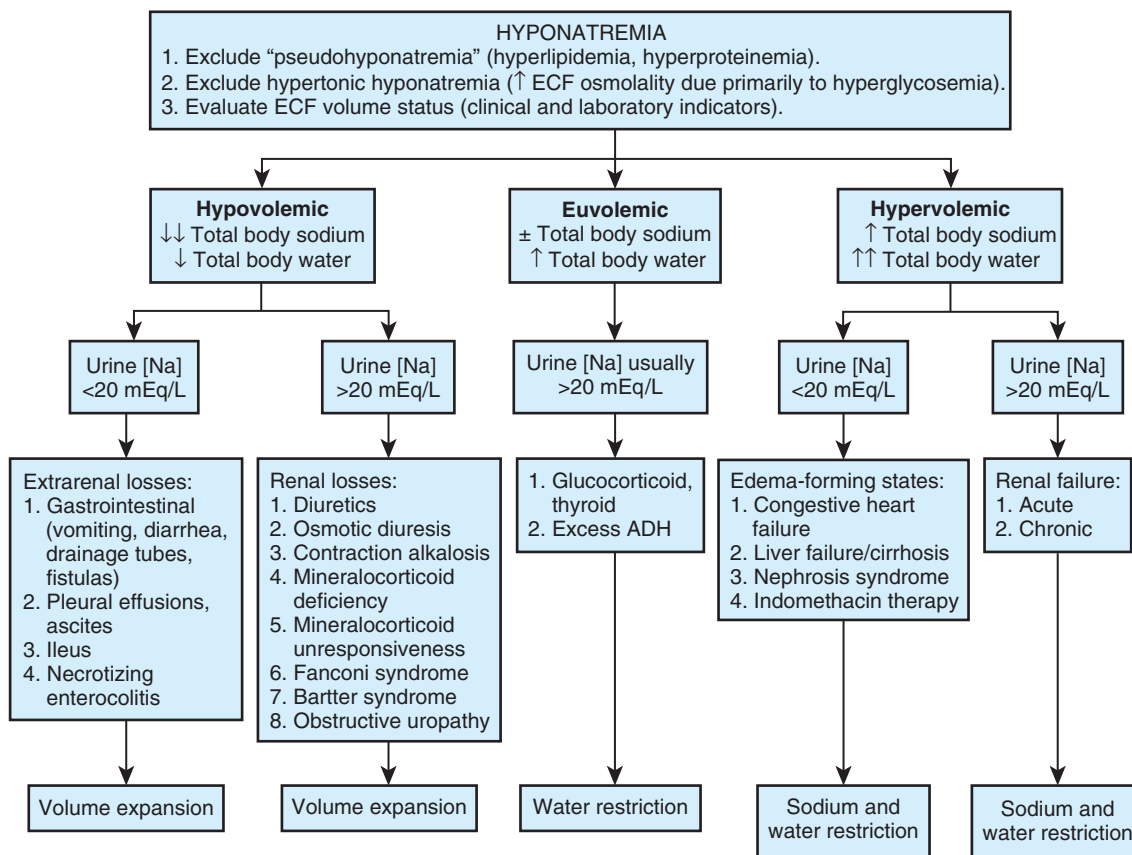

Sodium and Potassium Homeostasis and Management

Serum sodium values should generally be kept between 135 and 145 milliequivalent (mEq)/L. Sodium chloride supplementation of 1–2 mEq/kg per day should be started in preterm and sick term neonates only after completion of the postnatal extracellular volume contraction, usually after the first few days of age or after more than 5% of birth weight has been lost (Hartnoll et al., 2001). In general, as long as the neonate's fluid balance is stable, maintenance sodium requirements do not exceed 3–4 mEq/kg per day, and providing this amount usually ensures the positive sodium balance necessary for adequate growth. However, extreme prematurity and pathologic conditions associated with delayed transition or disturbance of fluid and electrolyte balance may significantly alter the neonate's daily sodium requirement. For example, although preterm neonates have a limited ability to excrete a sodium load (Hartnoll, 2003), they also may waste large amounts of sodium in their urine. In addition, neonates recovering from an acute renal insult and preterm neonates with immature proximal tubule functions who are in a state of extracellular volume expansion (Ramiro-Tolentino et al., 1996) may need daily sodium bicarbonate (NaHCO_3) supplementation to compensate for their greater renal bicarbonate losses.

Hyponatremia

Hyponatremia (serum sodium concentration <130 mEq/L) represents a deficit of sodium in relation to body water content and may be caused by either total body sodium (TBS) deficit or free water excess. In either situation, TBW may be decreased (hyponatremia with volume contraction), normal, or increased (hyponatremia with volume expansion). Chronic hyponatremia has been associated with adverse long-term outcomes, especially in preterm neonates, including increased incidence of sensorineural hearing loss and cerebral palsy (Murphy et al., 1997; Ertl et al., 2001). Although hyponatremia may primarily be a marker of illness severity, there is also evidence that sodium supplementation in preterm neonates is associated with better long-term outcomes, thus underscoring the importance of appropriate sodium management (Al-Dahhan et al., 2002).

Prevention of hyponatremia is the best approach in management; however, when hyponatremia occurs, to initiate effective treatment, it is important to attempt to determine the primary cause and duration of the hyponatremia and whether there is associated volume expansion or contraction. The most common cause of

• **Fig. 30.5** Flow diagram for the clinical evaluation of and therapy for neonates with hyponatremia. ADH, Antidiuretic hormone; ECF, extracellular fluid. (Modified from Avner ED. Clinical disorders of water metabolism: hyponatremia and hypernatremia. *Pediatr Ann.* 1995;24:23–30.)

hyponatremia in the sick neonate is excessive administration or retention of free water. In these situations the TBS content is normal, and the appropriate treatment is restriction of free water intake and not administration of sodium. In situations of true sodium deficit, one can estimate the deficits by assuming 70% of total body weight as the distribution space of sodium. The formula for calculating sodium (Na^+) deficit is:

$$\text{Na}^+ \text{ Deficit (or Excess) (mEq)} \approx 0.7 \times \text{Body Weight (kg)} \times ([\text{Na}^+]_{\text{desired}} - [\text{Na}^+]_{\text{current}}).$$

In most situations of depletion hyponatremia (i.e., true sodium deficit), two-thirds of the replacement sodium should be provided in the first 24 hours, and the remainder should be provided in the next 24 hours. Frequent measurements of serum levels of electrolytes are needed to ensure that the correction is occurring appropriately. With severe hyponatremia (serum sodium concentration <120 mEq/L), regardless of whether the hyponatremia is due to free water overload or TBS deficit, correction of the serum sodium concentration up to 120 mEq/L is recommended with administration of 3% saline solution (513 mEq of sodium per liter). This recommendation is due to concern of increased risk of neurologic complications associated with severe hyponatremia, although this relationship has not been explicitly demonstrated in large cohorts of neonatal patients (Riggs, 2002). This correction should be done over 4–6 hours, depending on the severity of hyponatremia (Avner, 1995), with use of the preceding formula and with close monitoring of serum sodium changes. Although

rapid IV bolus administration of 4–6 mL of 3% saline solution per kilogram has been effective in children with seizures or coma (Sarnaik et al., 1991), rapid and complete correction of low serum sodium concentration in adults with chronic hyponatremia have been shown to be associated with pontine and extrapontine myelinolysis (Nardone et al., 2016). Although this association has not been demonstrated in neonates, the potential risk of neurologic injury necessitates caution with rapid correction of long-standing hyponatremia. Once the serum sodium concentration has reached 120 mEq/L, complete correction of hyponatremia should be performed more slowly over the next 48 hours. In patients with asymptomatic hyponatremia whose serum sodium concentration exceeds 120 mEq/L, hypertonic infusions are not indicated. Additional therapy should be directed toward fluid restriction if the hyponatremia is dilutional or sodium repletion if the hyponatremia is depletional. For depletion hyponatremia, 5% dextrose in water with 0.45%–0.9% saline is a reasonable replacement fluid once the sodium is above 120 mEq/L. Chronic sodium losses in more stable neonates can also be corrected with enteral sodium chloride administration. Fig. 30.5 summarizes the clinical evaluation of and therapy for neonates with hyponatremia.

Hypernatremia

Hypernatremia (serum sodium concentration >150 mEq/L) reflects a deficiency of water relative to TBS and is most often a disorder of water rather than sodium homeostasis. The presence of hypernatremia does not reflect the TBS content, which can be high, normal, or low depending on the cause of the condition.

• BOX 30.2 Conditions Causing Hypernatremia**Hypovolemic Hypernatremia**

Inadequate breast milk intake
Diarrhea
Radiant warmers
Excessive sweating
Renal dysplasia
Osmotic diuresis

Euvolemic Hypernatremia**Decreased Production of Antidiuretic Hormone**

Central diabetes insipidus, head trauma, central nervous system tumors (craniopharyngioma), meningitis, or encephalitis

Decreased or Absence of Renal Responsiveness

Nephrogenic diabetes insipidus, extreme immaturity, renal insult, and medications such as amphotericin, hydantoin, and aminoglycosides

Hypervolemic Hypernatremia

Improperly mixed formula
Sodium bicarbonate administration
Sodium chloride administration
Primary hyperaldosteronism

Hypernatremia can also be associated with hypovolemia, normovolemia, or hypervolemia (Box 30.2). If hypernatremia is primarily due to changes in sodium balance, it can result from pure sodium gain or, more commonly, sodium gain coupled with a lesser degree of water accumulation or, rarely, water loss. It is important to recognize that neonates with hypernatremic dehydration often do not demonstrate overt clinical signs of intravascular depletion and dehydration until late in the course of the condition. The hypernatremia-induced hypertonicity causes water to shift from the intracellular to the extracellular compartment, resulting in intracellular dehydration but with relative preservation of the extracellular compartment. Compared with other organs, the CNS has a unique and more effective adaptive capacity to respond to the hypernatremia-induced hypertonicity, leading to a relative preservation of neuronal cell volume. The shrinkage of the brain stimulates the uptake of electrolytes such as sodium, potassium, and chloride (immediate effect). However, these electrolytes, at higher than normal intracellular concentrations, have severe adverse effects on intracellular enzyme functions. The concomitant, hypernatremia-induced and hyperosmolality-induced synthesis of osmoprotective amino acids and organic solutes (delayed response, starting perhaps around 4–6 hours into the process) thus serves as a defensive mechanism to protect cellular functions. These idiogenic osmols, such as taurine, glycine, glutamine, sorbitol, and inositol aid in maintaining normal brain cell volume during longer periods of hyperosmolar stress and limit the accumulation of intracellular sodium and chloride (Trachtman, 1991). As long as hypernatremia develops rapidly (within hours), as in accidental sodium loading, a relatively rapid correction of the condition is usually safe. Intracellular fluid accumulation does not occur because the accumulated electrolytes (sodium, potassium, and chloride) are rapidly extruded from the brain cells, and the development of cerebral edema is unlikely. In these cases, reducing serum sodium concentration by 1 mEq/L per hour (24 mEq/L per day) is appropriate (Adrogué and Madias, 2000).

In contrast to rapidly developing hypernatremia, in cases of chronic hypernatremia, the dissipation of idiogenic osmols in

response to correction of the hypernatremia occurs slowly over several days (Adrogué and Madias, 2000). Thus in these chronic cases, or in cases in which the time frame over which hypernatremia developed is unknown, the hypernatremia should be corrected more slowly, at a maximum rate of 0.5 mEq/L per hour (12 mEq/L per day). If correction is performed more rapidly in these cases, the abrupt fall in the extracellular tonicity results in the movement of water into the brain cells, which have a relatively fixed hypertonicity because of the presence of the osmoprotective molecules. The result is the development of brain edema with potentially deleterious consequences (Molteni, 1994; Adrogué and Madias, 2000). More recently, a large population-based study showed that neonates admitted to hospital with dehydration (weight loss >12% of birth weight) and hypernatremia (serum sodium concentration ≥ 150 mEq/L), but without shock, respiratory failure, infarct, or gangrene and in a managed care setting, did not have increased rates of adverse neurodevelopmental outcome at 5 years (Escobar et al., 2007). The authors noted that these favorable outcomes may not be generalizable to neonates presenting with more severe symptoms.

In the breastfed term neonate, hypernatremia most commonly develops in association with dehydration secondary to inadequate breast milk intake (Molteni, 1994) but has also been associated with high sodium levels in maternal breast milk, especially from mothers of neonates not successfully lactating (Peters, 1989; Abu-Salah, 2001; Karthikeyan and Modi, 2003; Scott et al., 2003). Reduction in breastfeeding frequency has been shown to be associated with a marked rise in the sodium concentration of breast milk (Neville et al., 1991). Thus the initial clinical presentation of neonates with breastfeeding-associated hypernatremia is a bodyweight loss of 10% or more, poor hydration state, lethargy, and poor feeding. Recognition may be delayed because these neonates may appear quiet and content initially, and, because of the slow development of the process, signs of extracellular volume contraction may be less prominent until the development of the full clinical presentation consisting of lethargy, irritability, hypotonia, and in some instances seizures, and cardiovascular collapse with renal failure. This presentation can be associated with serious CNS morbidity from both the hypertonicity (sagittal or other venous sinus thrombosis) and inappropriately rapid rehydration therapy (brain edema) (Lohr et al., 1989; van Amerongen et al., 2001). Although thorough follow-up studies of neonates with breastfeeding-associated severe hypernatremia are not available, observational studies suggest that up to 5% of these neonates experience brain damage (cerebral hemorrhage, edema, thrombosis or infarction) (Lavagno et al., 2016).

In the extremely immature neonate, early hypernatremia most commonly occurs from excessive transepidermal free water losses. The condition usually develops rapidly, within 24–72 hours after birth. The diagnosis is based on the attendant decrease in body weight, an increase in serum sodium concentration, and the clinical signs of extracellular volume contraction. Prevention of this condition can usually be accomplished by frequent monitoring of serum electrolyte levels, appropriate adjustments of free water intake, and the early use of humidified incubators (Modi, 2004). Application of ointments reduces TEWL but is associated with increased rates of sepsis and is thus not recommended (Edwards et al., 2004).

The central and nephrogenic forms of diabetes insipidus are much less common causes of hypernatremia and occur because of the lack of production of and renal responsiveness to vasopressin. Central diabetes insipidus can be congenital or can be acquired

secondary to neurologic insult (Chaudhary et al., 2011). Hypernatremia can also develop in response to excessive sodium supplementation, mainly in the sick neonate receiving repeated volume boluses for cardiovascular support or NaHCO_3 for metabolic acidosis. In these cases, clinical signs of edema, increased body weight, and the history of volume boluses help to establish the diagnosis.

Treatment of Hypernatremia. Thorough analysis of the medical history and the changes in clinical signs, laboratory findings, and body weight are necessary to determine the major etiologic factor in hypernatremia and thus the appropriate treatment. In the critically ill neonate, the cause of the serum sodium abnormality may be multifactorial, making the treatment strategy less straightforward. Although some cases of hypernatremia are a result of sodium excess with normal or high TBW, most cases in neonates are due to hypernatremic dehydration. Treatment of this condition is generally divided into two phases: the emergent phase, where the intravascular volume is restored, usually by administration of 10–20 mL of isotonic saline per kilogram, and the rehydration phase, where the sum of the remaining free water deficit and usual maintenance needs is administered evenly over at least 48 hours.

The free water deficit can be calculated as follows:

$$\text{H}_2\text{O Deficit (or Excess) (L)} \approx 0.7 \times \text{Body Weight (kg)} \times \left(\frac{[\text{Na}^+]_{\text{current}} (\text{mEq/L})}{[\text{Na}^+]_{\text{desired}} (\text{mEq/L})} - 1 \right).$$

In this formula, $(0.7 \times \text{body weight})$ is the estimation of TBW. When dehydration is diagnosed, correction should generally occur over 24 hours, with half of the correction occurring over the first 8 hours and the remainder over the next 16 hours. Longer correction times are indicated when dehydration is accompanied by moderate (serum sodium concentration >160 mEq/L) to severe (serum sodium concentration ≥ 175 mEq/L) hypernatremia, particularly when it is chronic as discussed earlier.

Alternatively, one can consider the amount of free water required to decrease the serum sodium concentration by a desired amount. The amount of free water required to decrease the serum sodium concentration by 1 mEq/L is 4 mL/kg with moderate hypernatremia but only 3 mL/kg when the serum sodium concentration is as high as 195 mEq/L (Molteni, 1994). Therefore the amount of free water required to decrease the serum sodium concentration by 12 mEq/L over a 24-hour period when hypernatremia is moderate (serum sodium concentration >160 mEq/L) is calculated as follows:

$$\text{Free Water Required} = \text{Current Weight (kg)} \times 4 \text{ mL/kg} \times 12 \text{ mEq/L}$$

or

$$\text{Free Water Required} = \text{Current Weight (kg)} \times 48 \text{ mL/kg per Day.}$$

The amount of free water required to decrease the serum sodium concentration by 12 mEq/L over a 24-hour period when hypernatremia is severe (serum sodium concentration >175 mEq/L) is calculated as follows:

$$\text{Free Water Required} = \text{Current Weight (kg)} \times 36 \text{ mL/kg per Day.}$$

The free water contents of the common IV fluids are listed in Table 30.2. It is important to note that sodium must be delivered with the free water replacement to avoid the hypernatremia being corrected too rapidly. In most mild to moderate hypernatremic

TABLE 30.2 Free Water Content (as Volume Percent) of Common Intravenous Solutions at Normal and High Serum Sodium Concentrations^a

| Intravenous Fluid | SERUM SODIUM CONCENTRATION | | | |
|----------------------------|----------------------------|-----------|--------------|-----------|
| | 145 mEq/L | | 195 mEq/L | |
| | Isotonic (%) | Water (%) | Isotonic (%) | Water (%) |
| 5% dextrose in water | 0 | 100 | 0 | 100 |
| 0.2% saline | 22 | 78 | 17 | 83 |
| 0.45% saline | 50 | 50 | 39 | 61 |
| 0.9% saline | 100 | 0 | 79 | 21 |
| Lactated Ringer's solution | 86 | 14 | 68 | 32 |

^aIsotonic saline provides 21% free water when given to a patient with a serum sodium concentration of 195 mEq/L and therefore will induce undesirable decreases in serum sodium concentration when used for volume resuscitation in the severely dehydrated hypernatremic neonate. Modified from Molteni KH. Initial management of hypernatremic dehydration in the breastfed infant. *Clin Pediatr*. 1994;33:731–740.

states (serum sodium concentration 150–160 mEq/L), during the rehydration phase, replacement fluids of 5% dextrose in 0.2% normal saline (31 mEq/L) or 0.45% normal saline (77 mEq/L) are appropriate. Infants with serum sodium levels greater than 165 mEq/L should initially be given 0.9% saline to avoid sudden drops in serum sodium concentration. When the serum sodium concentration is greater than 175 mEq/L, however, even normal saline will be hypotonic compared with the patient's serum. In these instances of severe hypernatremia, an appropriate amount of 3% saline (513 mEq/L) should be added to the IV fluid so that the sodium concentration in the fluid is approximately 10–15 mEq/L less than the serum sodium level (Rand and Kolberg, 2001). The relative free water content of an IV solution for a specific patient with sodium perturbations can be calculated with the formula:

Percentage of Free Water

$$= 1 - (\text{Intravenous Fluid Sodium} / \text{Serum Sodium}).$$

Serum electrolyte levels should be monitored every 2–4 hours until the desired rate of decline in serum sodium concentration is established. At this point, the frequency of the laboratory measurements can be relaxed to every 4–6 hours until the serum sodium concentration is less than 150 mEq/L. The speed of correction of hypernatremia depends on the rate of its development. This approach provides a reasonable chance that the serum sodium concentration will gradually decrease to the normal range over 2–4 days. Except in cases of acute massive sodium overload, the goal should be to lower the serum sodium concentration at a rate no greater than 1 mEq/L per hour. A slower pace of correction of 0.5 mEq/L per hour is prudent in patients with hypernatremia of chronic or unknown duration to avoid iatrogenic CNS sequelae.

While free water deficits are being corrected, the usual maintenance fluids and electrolytes must also be provided. Ongoing urine losses should be replaced volume for volume every 4–6 hours with a solution tailored to the urine's electrolyte concentration (usually 0.225%–0.45% normal saline). Extraordinary losses caused by open wounds, tubes, drains, ostomies, emesis, and/or diarrhea

TABLE 30.3 Approximate Electrolyte Composition of Body Fluids (mEq/L)

| Body Fluid | Sodium | Potassium | Chloride |
|-----------------|---------|-----------|----------|
| Gastric | 20–80 | 5–20 | 100–150 |
| Small intestine | 100–140 | 5–15 | 90–130 |
| Bile | 120–140 | 5–15 | 80–120 |
| Ileostomy | 45–135 | 3–15 | 20–115 |
| Diarrhea | 10–90 | 10–80 | 10–110 |

should always be considered in the dehydrated or hypernatremic infant and also accounted for in fluid management. The composition of this latter replacement solution depends on the electrolyte concentration of the fluid loss. The most common extraordinary loss, gastric fluid, contains significant amounts of sodium and chloride. See [Table 30.3](#) for approximate electrolyte compositions of body fluids. Because of the association between hyponatremia and neurologic injury in hospitalized pediatric patients ([Moritz and Ayus, 2003](#)), thoughtful consideration of fluid tonicity must be considered when the replacement fluid composition is being determined in the treatment of hypernatremia. Some have advocated routine administration of isotonic (“normal” saline) fluids regardless of sodium requirement to avoid “hospital-acquired hyponatremia” caused by overadministration of free water ([Moritz and Ayus, 2003](#); [Powell, 2015](#)). This approach is not without risk, given the overdose of sodium that occurs with administration of normal saline ([Holliday et al., 2004, 2007](#)). A more reasonable approach may be to base the appropriate fluid prescription on accurately assessed fluid deficits and ongoing requirements, with thoughtful consideration of sodium requirements of each compartment, as well as frequent monitoring of serum sodium changes ([Holliday et al., 2004, 2007](#)).

Once serum sodium concentration, urine output, and renal function are normal, the patient should receive standard maintenance fluids, either intravenously or orally, depending on his or her condition. Potassium replacement (usually by addition of 20–40 mEq of potassium per liter of replacement fluid) should not begin until adequate urine output has been established. At this time, electrolyte status must still be monitored for an additional 24 hours to ensure that complete recovery has occurred. Hyperglycemia and hypocalcemia commonly accompany hypernatremia. The use of insulin to treat the hyperglycemia is not recommended, because it can increase brain idiogenic osmol content. Hypocalcemia should be corrected with appropriate calcium supplementation.

Potassium Homeostasis and Management

Serum potassium concentration should be kept between 3.5 and 5 mEq/L. In the early postnatal period, neonates, especially immature preterm neonates, have higher serum potassium concentrations than older persons. The cause of the relative hyperkalemia of the newborn is multifactorial and involves developmentally regulated differences in renal function, sodium potassium–adenosine triphosphatase activity ([Vasarhelyi et al., 2000](#)), and hormonal milieu. Exposure to steroids prenatally in premature neonates is associated with a decreased incidence of hyperkalemia, believed to be due to improved renal function ([Omar et al., 2000](#)).

In general, potassium supplementation should be started only after urine output has been well established, usually by the third

postnatal day. Supplementation should be started at 1–2 mEq/kg per day and increased over 1–2 days to the usual maintenance requirement of 2–3 mEq/kg per day. Some preterm neonates may need more potassium supplementation after the completion of their postnatal volume contraction because of their increased plasma aldosterone concentrations, prostaglandin excretion, and disproportionately high urine flow rates. Most neonates will require additional potassium supplementation if they are receiving diuretics.

Hypokalemia. Hypokalemia in the neonate is usually defined as a serum potassium level of less than 3.5 mEq/L. Hypokalemia can occur from potassium loss due to diuretics, diarrhea, renal dysfunction, or nasogastric drainage from inadequate potassium intake or from shift of potassium into the intracellular compartment in the presence of alkalosis. Electrocardiogram (ECG) manifestations of hypokalemia include flattened T waves, prolongation of the QT interval, or the appearance of U waves. Except in patients receiving digoxin, hypokalemia is rarely symptomatic until the serum potassium concentration is less than 2.5 mEq/L. This degree of hypokalemia can result in cardiac arrhythmias, ileus, and lethargy.

Treatment of Hypokalemia. Hypokalemia is treated by slow replacement of potassium either intravenously or orally, usually in the daily fluids. Rapid administration of potassium chloride is not recommended because it may be associated with life-threatening cardiac dysfunction. In extreme emergencies, potassium can be given as an infusion over 30–60 minutes of not more than 0.3 mEq of potassium chloride per kilogram. If hypokalemia is secondary to alkalosis, the total body potassium content is usually normal, and the alkalosis should be corrected before an increase in the potassium intake is considered.

Hyperkalemia. Hyperkalemia in the neonate is defined as a serum potassium level greater than 6 mEq/L in a nonhemolyzed specimen. It is important to understand that most of the body’s potassium is contained within cells; therefore serum potassium levels do not accurately reflect total body stores. However, a serum potassium level greater than 6.5 to 7 mEq/L can be life threatening, even if total body stores are normal or low, because of its effect on cardiac rhythm. ECG manifestations of hyperkalemia include peaked T waves (the earliest sign), a widened QRS configuration, bradycardia, tachycardia, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation. Because pH affects the distribution of potassium between the intracellular and the extracellular space, serum potassium levels may rise acutely during acidosis. The clinician should be aware of the potential for life-threatening arrhythmias to occur in infants with chronic lung disease receiving diuretics and potassium supplements who develop a sudden respiratory deterioration with acidosis.

Hyperkalemia is very common in the very preterm neonate, occurring in more than 50% of neonates weighing less than 1000 g ([Mildenberger and Versmold, 2002](#)). Another common cause of hyperkalemia is renal dysfunction, of particular concern in very preterm neonates and in neonates whose course is complicated by asphyxia or hypotension. In addition, hyperkalemia secondary to release of potassium from dying cells often complicates IVH, tissue ischemia (i.e., volvulus or necrotizing enterocolitis), and intravascular hemolysis. Less commonly, hyperkalemia may be one of the earliest manifestations of congenital adrenal hyperplasia or may occur because of other causes of neonatal acute adrenal insufficiency.

Treatment of Hyperkalemia. When hyperkalemia is diagnosed, all potassium intake should be discontinued, and the ECG should

TABLE 30.4 Medications Used for Treatment of Hyperkalemia

| Medication | Dosage | Onset | Length of Effects | Mechanism of Action | Comments and Cautions |
|------------------------|---|-----------------------------|-------------------|--|--|
| Calcium gluconate | 100 mg/kg intravenously over 2–5 min | Immediate | 30 min | Protects the myocardium from toxic effects of potassium; no effect on total body potassium | Can worsen digoxin toxicity |
| Sodium bicarbonate | 1–2 mEq/kg | Immediate | Variable | Shifts potassium intracellularly; no effect on total body potassium | Maximum infusion: mEq/min in emergency situations |
| Tromethamine | 3–5 mL/kg | Immediate | Variable | Shifts potassium intracellularly; no effect on total body potassium | — |
| Insulin plus dextrose | Insulin 0.1–0.15 U/kg intravenously plus dextrose 0.5 g/kg intravenously | 15–30 min | 2–6 h | Shifts potassium intracellularly; no effect on total body potassium | Monitor for hypoglycemia |
| Albuterol ^a | 0.15 mg/kg every 20 min for three doses then 0.15–0.3 mg/kg | 15–30 min | 2–3 h | Shifts potassium intracellularly; no effect on total body potassium | Minimum dose 2.5 mg |
| Furosemide | Per os: 1–4 mg/kg per dose once or twice per day Intravenously: 1–2 mg/kg per dose given every 12–24 h | 15 min to 1 h | 4 h | Increases renal excretion of potassium | — |
| Sodium polystyrene | 1 g/kg rectally every 6 h | 1–2 h (rectal route faster) | 4–6 h | Removes potassium from the gut in exchange for sodium | Use with extreme caution in neonates, especially preterm neonates; contains sorbitol; may be associated with bowel necrosis and sodium retention |

^aFrom Singh BS, Sadiq HF, Noguchi A, Keenan WJ. Efficacy of albuterol inhalation in treatment of hyperkalemia in premature neonates. *J Pediatr*. 2002;141:16–20.

be monitored. [Table 30.4](#) presents medications used in management of significant hyperkalemia. Calcium gluconate stabilizes cardiac membranes, and alkali therapy (sodium bicarbonate), insulin/glucose, and inhaled albuterol ([Singh et al., 2002](#)) all rapidly enhance cellular uptake of potassium and can cause a sharp drop in serum potassium levels in life-threatening situations but will not decrease total body potassium content. Intravenously administered furosemide and rectally administered sodium polystyrene sulfonate (Kayexalate) enhance potassium excretion and will lower total body stores but require at least several hours to take effect. Furthermore, use of polystyrene sulfonate to treat hyperkalemia in preterm neonates (<29 weeks' gestational age or <1250 g birth weight) has been associated with intestinal complications, including hematochezia and necrotizing enterocolitis ([Milley and Jung, 1995](#); [Rugolotto et al., 2007](#)). Dialysis or exchange transfusion may be used when the hyperkalemia is life threatening and other measures do not result in relief.

Clinical Conditions Associated With Fluid and Electrolyte Disturbances

Extreme Prematurity

Infants born between 23 and 27 weeks' gestation, or with a birth weight of less than 1000 g (i.e., ELBW), are at particular risk of acute abnormalities of both fluid and electrolyte status in the immediate postnatal period. TEWL is much higher than in more

mature preterm neonates (see [Fig. 30.4](#)), and thus it is difficult for water balance to be maintained unless this water loss is prevented. Historically, when ELBW infants were cared for in an open warmer without the use of a plastic heat shield or a humidified incubator, up to 150–300 mL of free water per kilogram per day could be lost through the skin during the first 3–5 days of postnatal life. Neonates whose mothers received glucocorticoids prenatally often have fewer problems because prenatally administered glucocorticoids enhance maturation of the epidermis and cardiovascular and renal function, resulting in increases in urine output and fractional excretion of sodium ([Omar et al., 1999](#); [Ali et al., 2000](#)).

Because serum sodium concentration is a reliable clinical indicator of extracellular tonicity, monitoring of this parameter every 6–12 hours during the first 2–3 days postnatally coupled with daily (or twice daily) measurements of body weight provides valuable information and appropriate guidance for the fluid and electrolyte management of the extremely immature preterm neonate. Serum osmolality may be directly measured in patients in whom calculated serum osmolality is more than 300–320 mOsm/L.

[Table 30.1](#) shows suggested maintenance fluid requirements by birth weight and postnatal day of life. Because immature neonates in an incubator with an ambient air humidity of 50%–80% require significantly less free water and less frequent measurements of serum electrolyte and osmolality ([Sedin, 1995](#)), open radiant warmers should rarely be used for these patients. Their initial parenteral fluid should contain between 5%–10% dextrose, protein

concentrations of 2.5–3.5 g/kg, and maintenance calcium, with no additional sodium or potassium. Fluid intake is then increased by 10–30 mL/kg per day every 6–12 hours if the serum sodium concentration rises from the baseline, the goal being to keep the serum sodium concentration below 145–150 mEq/L. As skin integrity improves during the course of the second to third days, serum sodium concentration starts to fall. At this time, a stepwise reduction in total fluid intake is obligatory to allow a complete contraction of the extracellular volume to occur and to minimize the possibility of free water overload with its attendant enhanced risks for the development of ductal patency, pulmonary edema, and worsening lung disease.

Critically ill, extremely immature neonates often receive excess sodium with volume boluses, medications, and the maintenance infusion of their arterial lines. Therefore extra sodium supplementation should usually not be started during the first few postnatal days, to prevent a rise in TBS concentration and thus extracellular volume, which will hinder the appropriate postnatal diuresis. However, one must be careful as a positive sodium balance is a prerequisite for appropriate growth, and thus after the transitional period, it must be ensured. Potassium chloride supplementation may be started as soon as urine output has been established and the serum potassium concentration is less than 5 mEq/L. Extremely premature neonates are at risk of the development of both oliguric and nonoliguric hyperkalemia, so the serum potassium concentration should be monitored closely, and supplementation should be discontinued if warranted by changes in serum potassium values or in renal function.

Many critically ill preterm neonates retain their originally high extracellular volumes, even when sodium and water intakes are restricted, and such neonates also tend to lose more bicarbonate in the urine. Proximal tubular bicarbonate reabsorption may be gestation-age appropriate even in the VLBW neonate despite the immaturity of its renal function, as long as extracellular volume contraction occurs (Ramiro-Tolentino et al., 1996). Therefore the presence of the extracellular volume expansion appears to be an important factor in the renal bicarbonate wasting in these neonates. The diagnosis of functional proximal tubular acidosis in such cases should not rely solely on the finding of an alkaline urine pH, because the distal tubular function is usually mature enough to acidify the urine once the serum bicarbonate concentration has decreased to its new threshold. Provided that liver function is normal, daily supplementation of bicarbonate, in the form of sodium acetate, potassium acetate, or both, rapidly begins to normalize blood pH and serum bicarbonate concentration in these neonates and also increases urine pH, aiding in the diagnosis. Once extracellular volume contraction occurs, these neonates generally achieve a positive bicarbonate balance (Ramiro-Tolentino et al., 1996), and supplementation becomes unnecessary.

Other general guidelines in the fluid and electrolyte management of the immature preterm neonate during the first postnatal week are (1) daily calculation of fluid balance and estimation of sodium balance, (2) daily measurements of body weight, serum electrolyte levels, and plasma glucose levels, and (3) testing of urine samples for glucose and osmolality or specific gravity. The frequency of testing and the addition of other tests, including the measurement of serum albumin concentration and osmolality, depend on the clinical status, the severity of the underlying disease, and the fluid and electrolyte disturbance of the individual patient. Serum creatinine and especially BUN levels are not accurate measures of fluid status in the first postnatal weeks, but following their trend can be helpful. There is little to no association between BUN levels

and protein intake (Ridout et al., 2005), even when changes in renal function are taken into account (Weintraub et al., 2015).

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn is a self-limited respiratory complication in term and late preterm neonates caused by delayed clearance of fetal lung fluid in the immediate postdelivery period. These neonates present with mild to moderate respiratory distress frequently requiring supplemental oxygen and distending pressure provided by a nasal cannula, a high-flow nasal cannula, or continuous positive end-expiratory pressure for a duration ranging from 24–96 hours.

Fluid management for these patients can impact the duration of their illness. In one study, for late preterm and term neonates requiring respiratory support for greater than 48 hours (“severe” transient tachypnea of the newborn), patients with restricted fluid intake (40 mL/kg per day in term neonates and 60 mL/kg per day in late preterm neonates) compared with standard fluid intake (60 mL/kg per day in term neonates and 80 mL/kg per day in late preterm neonates) had decreased time on respiratory support, decreased hospital costs, and a trend toward decreased length of stay. There was no increase in hypoglycemia (defined as a blood glucose concentration <40 mL/dL) or other factors potentially affecting the safety of care (Stroustrup et al., 2012).

Respiratory Distress Syndrome

There is a well-established relationship between fluid and electrolyte imbalance and RDS. Surfactant deficiency results in pulmonary atelectasis, elevated pulmonary vascular resistance, poor lung compliance, and decreased lymphatic drainage. In addition, preterm neonates have low plasma oncotic and critical pulmonary capillary pressures and experience pulmonary capillary endothelial injury from mechanical ventilation, oxygen administration, and perinatal hypoxia (Sola and Gregory, 1981; Dudek and Garcia, 2001). These abnormalities alter the balance of the Starling forces in the pulmonary microcirculation, leading to interstitial edema formation, with further impairment in pulmonary functions.

In the presurfactant era, an improvement in pulmonary function occurred only during the third to fourth postnatal day. This improvement was usually preceded by a period of brisk diuresis characterized by small increases in glomerular filtration rate and sodium clearance and a larger rise in free water clearance (Costarino and Baumgart, 1991). Although the exact mechanism for this diuresis is not known, it is likely that improving endogenous surfactant production and capillary integrity promoted the recovery of the pulmonary capillary endothelium and lymphatic drainage. The ensuing changes in Starling forces then favored reabsorption of the hypotonic interstitial lung fluid into the circulation, increasing intravascular volume and organ perfusion, followed by the delayed “physiologic” diuresis. Prenatal administration of steroids and postnatal use of surfactants have clearly altered the course and clinical presentation of RDS (Kari et al., 1994; Ballard and Ballard, 1995; Carlton et al., 1995).

Bronchopulmonary Dysplasia

BPD is a multifactorial disease. Many risk factors have been associated with the development of BPD, including a high fluid and salt intake during the first few days to weeks of postnatal life. Specifically, higher fluid intake and lack of appropriate weight loss during the first 10 postnatal days are associated with significantly higher risk of BPD, even after other known risk factors have been controlled for (Oh et al., 2005). Furthermore, a recent study

found an association between a neonate's cumulative fluid intake in neonates with an intake of more than 345 mL/kg in the second through fourth postnatal days and an increased incidence of severe BPD (Guo et al., 2015). Therefore careful fluid and electrolyte management during the first few weeks of life, allowing the appropriate degree of weight loss, are of great importance in decreasing the incidence and severity of this condition (see Chapter 48).

Patent Ductus Arteriosus and Treatment With Indomethacin/Ibuprofen

Fluid, electrolyte, and acid–base management can affect the PDA, as increased fluid administration, increases in extracellular volume, and metabolic acidosis prolong patency of the ductus arteriosus (Hammerman, 1995; see Chapter 54). Accordingly, clinical management aimed at preventing the occurrence of ductal patency involves thoughtful management of fluid and electrolyte balance (Clyman, 1996).

In the preterm neonate, indomethacin administration has been shown to have clinically significant, although mostly transient, renal side effects because of decreased prostaglandin production through inhibition of cyclooxygenase. In the indomethacin-treated neonate, the unopposed renal vasoconstriction and sodium and water reabsorption lead to decreases in renal blood flow and glomerular filtration rate and to increases in sodium and free water reabsorption. These side effects occur despite the diminishing left-to-right shunt through the closing ductus. Characteristic clinical findings include a rise in serum creatinine level, oliguria, and hyponatremia (Cifuentes et al., 1979). Hyponatremia occurs because the free water retention caused by the unopposed renal actions of high plasma vasopressin levels is out of proportion to the sodium retention induced by angiotensin and noradrenaline. Fluid management of the preterm neonate receiving indomethacin must focus on maintaining an appropriately restricted fluid intake and avoiding extra sodium supplementation until urine output increases and renal function recovers. As the prostaglandin inhibitory effects of indomethacin diminish following the last dose, renal prostaglandin production returns to normal, and the retained sodium and excess free water are usually rapidly excreted, especially with the improvement in cardiovascular status as the ductal shunt decreases.

Ibuprofen is an alternative inhibitor of cyclooxygenase for the treatment of PDA and appears to have equivalent efficacy in closing the symptomatic PDA, with fewer adverse effects (Ohlsson et al., 2015). Specifically, ibuprofen administration is associated with less renal and gastrointestinal (GI) dysfunction (Van Overmeire et al., 2000) and no apparent effect on cerebral perfusion (Mosca et al., 1997; Patel et al., 2000). The lack of an effect on cerebral perfusion likely explains why prophylactic ibuprofen does not reduce the incidence of severe IVH (Ohlsson and Shah, 2015). For more details, see Chapter 61.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

In the preterm and term newborn, SIADH may be associated with birth asphyxia, intracerebral hemorrhage, RDS, pneumothorax, and the use of continuous positive pressure ventilation (El-Dahr and Chevalier, 1990; Hidalgo-Mora et al., 2011). It has also been described in relation to infectious diseases, including meningitis, bronchiolitis, and pneumonia. The syndrome is characterized by oliguria, free water retention, decreased serum sodium concentration and serum osmolality, increased urine concentration, and weight gain caused by edema formation. However, because the urinary concentrating capacity of the newborn is limited, a less than

maximally diluted urine satisfies the diagnosis of SIADH in the presence of the other symptoms. The treatment is based on fluid and sodium restriction despite the oliguria and hyponatremia, as well as on appropriate circulatory and ventilatory support. The clinician must remember that TBS content is normal, but TBW content is elevated in such a neonate, and that it is particularly dangerous to treat the hyponatremia caused by free water retention with large amounts of sodium. Because of their more immature renal function, ELBW neonates during the first few weeks of postnatal life usually do not exhibit the full-blown syndrome despite their sometimes excessively high plasma vasopressin levels (Aperia et al., 1983).

Diminished vasopressin secretion or complete unresponsiveness of the renal tubules to vasopressin results in polyuria, dilute urine production, and increased serum osmolality (Werny et al., 2015), otherwise known as *diabetes insipidus*. This condition is not common in neonates but can occur in association with CNS injury or disease, such as in meningitis, in cerebral hemorrhage affecting the pituitary gland (central diabetes insipidus), or in an inherited form (nephrogenic diabetes insipidus). In addition, diabetes insipidus is one of the features of congenital developmental abnormalities also affecting the pituitary gland, such as septo-optic dysplasia (de Morsier syndrome). The treatment of neonates with this condition consists of facilitating adequate free water intake and the use of desmopressin with or without chlorothiazide (Nofal and Lteif, 2015).

Surgical Conditions

Surgery has a major effect on metabolism, fluid balance, and electrolyte balance in the newborn. Preterm neonates with acute or chronic lung disease are especially sensitive and respond to the procedure with significant catabolic responses, increases in capillary permeability, with the attendant shift of fluid into the interstitial space, and retention of sodium and free water (John et al., 1989). The retention of sodium and free water is secondary to the decrease in effective circulating blood volume and to the increased plasma levels of sodium-retaining and water-retaining hormones, including catecholamines, renin–angiotensin–aldosterone, and vasopressin.

Preoperative management has a significant effect on outcome and should aim at maintaining adequate effective circulating blood volume as well as cardiovascular and renal function. In preterm neonates who have evidence of absolute or relative adrenal insufficiency (Watterberg, 2002), as well as those who have received prolonged steroid therapy for hypotension or lung disease, the provision of stress doses of steroids may be necessary. In the postoperative period, appropriate close monitoring and maintenance of the integrity of the cardiovascular system through the judicious use of volume expanders and vasopressor–inotropic support, if required, meticulous replacement of ongoing surgical and nonsurgical fluid and electrolyte losses, close monitoring, and intense and effective communication between the neonatal team and the surgical team are essential to ensure a successful outcome. As capillary integrity improves, reabsorption and excretion of the expanded interstitial fluid volume occurs, with normalization in the secretion of hormones regulating fluid and electrolyte balance. At this time the provision of maximized nutritional support becomes essential to restore the anabolic state and growth of the neonate.

The most commonly encountered surgical water losses occur when a nasogastric tube is placed under continuous suction to provide relief for the GI tract in conditions such as necrotizing enterocolitis and postoperative management after abdominal surgery. Because these losses may be substantial, they should be monitored

and a portion of the losses should be replaced every 6–12 hours to maintain appropriate water and electrolyte balance. However, free water retention often develops after surgery; therefore full replacement of the nasogastric free water loss is not usually recommended. One of the approaches to the fluid–electrolyte management of postoperative neonates may be to replace half of the removed/lost volume or increase the total fluid limit for a period to account for these losses. The composition of the replacement solution depends on the electrolyte concentration of the fluid loss. Gastric fluid usually contains 50–60 mEq of sodium chloride per liter, and therefore 0.45% sodium chloride with potassium is normally used as the fluid of choice for replacement. See Table 30.3 for estimated electrolyte compositions of body fluids.

Acid–Base Balance

Physiology of Acid–Base Balance Regulation

Like adults, newborns must maintain their extracellular pH, or hydrogen ion concentration, within a narrow range. A normal pH is essential for intact functioning of all enzymatic processes and therefore the intact functioning of all organ systems of the body. Newborns are subjected to many stresses that can affect their acid–base balance. In addition, neonates, especially if they are premature, have a limited ability to compensate for acid–base alterations; therefore acid–base disturbances are common in the neonatal period. An understanding of the principles of acid–base regulation is essential for proper diagnosis and treatment of these disturbances.

In healthy humans, the normal range of ECF hydrogen ion (H^+) concentration is 35–45 mEq/L. Because pH is defined as the negative logarithm of hydrogen ion concentration ($pH = -\log[H^+]$), these hydrogen ion concentrations correspond to a pH range of 7.35–7.45. Acidosis is a downward shift in pH to less than 7.35, and alkalosis is an upward shift in pH to more than 7.45. Alterations in normal pH are resisted by complex physiologic regulatory mechanisms. The main systems that maintain pH are the body's buffer systems, the respiratory system, and the kidneys. Some of these systems respond immediately to sudden alterations in hydrogen ion concentration, whereas others respond more slowly to changes but maintain the overall balance between acid and base production, intake, metabolism, and excretion over the long term.

The physiologic regulatory systems that respond immediately to changes in acid–base balance include the various intracellular and extracellular buffers as well as the lungs. A buffer is a substance that can minimize changes in pH when acid or base is added to the system. The extracellular buffers, which include the bicarbonate–carbonic acid system, phosphates, and plasma proteins, act rapidly to return the extracellular pH toward normal. The intracellular buffers, which include hemoglobin, organic phosphates, and bone apatite, act more slowly and require several hours to reach maximal capacity.

The most important extracellular buffer is the plasma bicarbonate–carbonic acid buffer system, in which the acid component (carbonic acid [H_2CO_3]) is regulated by the lungs, and the base component (bicarbonate [HCO_3^-]) is regulated by the kidneys. The buffer equation is as follows:

where $(CO_2)_d$ represents the dissolved carbon dioxide. At equilibrium, the amount of dissolved CO_2 exceeds that of H_2CO_3 by a factor of 800:1; therefore for practical purposes, dissolved CO_2

and H_2CO_3 can be treated interchangeably. The fact that CO_2 excretion can be controlled by the respiratory system markedly increases the efficiency of this buffer system at physiologic pH. The enzyme carbonic anhydrase allows rapid interconversion of H_2CO_3 to H_2O and CO_2 . If the hydrogen ion (H^+) concentration increases for any reason, hydrogen combines with HCO_3^- , driving the buffer reaction toward greater production of H_2CO_3 and CO_2 . CO_2 crosses the blood–brain barrier and stimulates CNS chemoreceptors, leading to increased alveolar ventilation and decreased concentration of extracellular CO_2 . This respiratory compensation begins within minutes after a pH change and is complete within 12–24 hours. A similar compensation occurs in response to a decrease in H^+ concentration, leading to decreased alveolar ventilation and a resultant increase in extracellular CO_2 concentration.

The relationship between the two components of the bicarbonate–carbonic acid buffer system and pH is expressed by the Henderson–Hasselbalch equation:

$$pH = pK_a + \log \left(\frac{[HCO_3^-]}{[H_2CO_3]} \right).$$

Because H_2CO_3 is in equilibrium with the dissolved CO_2 in the plasma, and because the amount of dissolved CO_2 depends on the partial pressure of CO_2 , the equation can be modified as follows:

$$pH = pK_a + \log \left(\frac{[HCO_3^-]}{0.03} \right) \times PaCO_2.$$

Both the original equation and the modified equation are clinically difficult to use; therefore the modified Henderson–Hasselbalch equation can be rewritten as the Henderson equation without logarithms for easier clinical use:

$$[H^+] = 24 \times \frac{PaCO_2}{[HCO_3^-]}.$$

This last equation clearly describes the clinically most important aspect of acid–base regulation by the bicarbonate–carbonic acid buffer system, that the change in the ratio of $PaCO_2$ to HCO_3^- concentration, and not in their absolute values, determines the direction of change in H^+ concentration and thus in pH. The status of the plasma bicarbonate–carbonic acid buffer system can be monitored easily by serial blood gas measurements, making understanding of this buffer system important in clinical care.

The physiologic regulation system that responds more slowly to changes in acid–base balance is the renal system. There must be a long-term balance between net acid increase caused by intake and production and net acid decrease caused by excretion and metabolism. Although infant formula and protein-containing IV fluids have small amounts of preformed acid, most of the daily acid load is derived from metabolism. A large amount of the acid produced is in the form of the volatile H_2CO_3 , which can be excreted in the lungs. Nonvolatile or fixed acids are also produced and must be excreted through the kidneys. The nonvolatile acids are normally sulfuric acid produced in the metabolism of the amino acids methionine and cysteine and, to a lesser extent, phosphoric acid, lactic acid, hydrochloric acid, and incompletely oxidized organic acids. In addition to the excretion of nonvolatile acids, however, the kidneys have a role in long-term acid–base regulation by controlling renal HCO_3^- excretion.

Two regions of the kidney act to achieve urinary acidification: the proximal tubule and the collecting tubule. The proximal tubule acidifies the urine by two mechanisms. The first mechanism is by the reabsorption of any HCO_3^- already present in the blood that

is being constantly filtered through the glomeruli. The proximal tubule reabsorbs 60%–80% of all filtered HCO_3^- and performs this role through the exchange of Na^+ for H^+ across the luminal membrane of the proximal tubular cells via the Na^+/H^+ exchanger. The excreted H^+ combines with filtered HCO_3^- , producing H_2CO_3 through the activity of carbonic anhydrase in the cellular brush border. The H_2CO_3 is then quickly converted to CO_2 , which crosses into the tubular cell, where HCO_3^- is regenerated and reabsorbed back into the bloodstream, mostly in exchange for chloride (Cl^-). The regenerated H^+ ion reenters the cycle at the Na^+/H^+ exchanger.

The second mechanism by which the proximal tubule acidifies urine is by the production of ammonia (NH_3). Inside the tubular cell, NH_3 is produced by the deamination of glutamine. The NH_3 is secreted into the tubular lumen, where it combines with and traps free H^+ to form ammonium (NH_4^+).

The remaining urinary acidification occurs mostly in the collecting tubule. H^+ secreted in this region of the kidney is sufficient to combine with or titrate any remaining filtered HCO_3^- or any filtered anions, such as phosphate and sulfate. Hydrogenated phosphate and sulfate anions produce the titratable acid of the urine. The collecting tubule also takes up NH_3 from the medullary interstitium and secretes it into the urine, where again it can combine with and trap H^+ as NH_4^+ . This urinary NH_4^+ can act as a cation and can be excreted with urinary anions such as Cl^- , phosphate (PO_4^-), and sulphate (SO_4^-), thereby preventing loss of cations such as Na^+ , Ca^{2+} , and K^+ . Total acid secretion in the kidney can be represented by

$$\text{Titratable Acid} + \text{NH}_4^+ - \text{HCO}_3^-$$

and under normal conditions should equal the net production of acid from the diet and metabolism that is not excreted in the form of CO_2 through the lungs.

In adults, the steady state for renal compensation for respiratory alkalosis is reached within 1–2 days and that for respiratory acidosis is reached within 3–5 days. Newborns are able to compensate for acidemia through the previously described renal mechanisms, although the renal response to acid loads is limited, especially in premature neonates born before 34 weeks' gestation. Reabsorption of HCO_3^- in the proximal tubule and distal tubular acidification are also decreased, with a fairly rapid gestational age-dependent maturation of these functions after birth (Jones and Chesney, 1992).

To accomplish the tight regulation of pH necessary for survival, H^+ ions generated in the form of the volatile acid H_2CO_3 are excreted by the lungs as CO_2 . H^+ ions generated in the form of nonvolatile acids are buffered rapidly by extracellular HCO_3^- and more slowly by intracellular buffers. HCO_3^- is then replenished by the kidneys via the reabsorption of much of the filtered HCO_3^- and by the excretion of H^+ in the urine as NH_4^+ and titratable acids.

Disturbances of Acid–Base Balance in the Newborn

General Principles

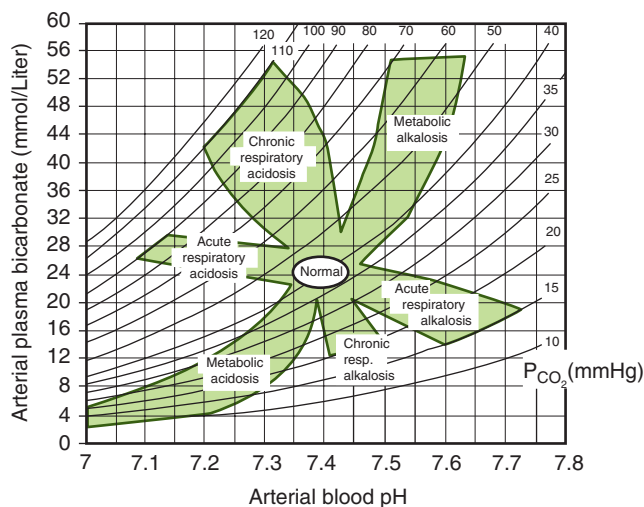

The evaluation of the acid–base status in a newborn is one of the most common laboratory assessments made in the neonatal intensive care unit. The status of this system can be monitored with blood gas measurements and should be the starting point for the evaluation of any acid–base disorder. In the blood gas measurement, the pH and PaCO_2 levels are directly measured; from these, the HCO_3^- level and base excess or deficit are calculated.

The whole blood buffer base, defined as the sum of the HCO_3^- and non- HCO_3^- buffer systems, is another important blood gas value used in evaluating acid–base disturbances. The difference between the observed whole blood buffer base of any blood gas sample and the expected normal buffer base of that sample is called the base excess or base deficit. The base excess and base deficit give an accurate measure of the amount of strong acid or base respectively that would be needed to titrate the pH back to normal once the respiratory contribution of the acid–base disturbance is also corrected. For example, a base excess of 10 mEq/L indicates that there is an additional 10 mEq of base per liter (or loss of 10 mEq of H^+ per liter) that is contributing to the acid–base abnormality. Conversely, a base deficit of 10 mEq/L indicates there is relatively more acid (or less base) in the ECF than expected after the effect of PaCO_2 on pH has been accounted for.

Acid–base disorders are classified according to their cause as being either metabolic or respiratory. Metabolic acidosis occurs as a result of the accumulation of increased amounts of nonvolatile acid or decreased amounts of HCO_3^- in the ECF. Metabolic alkalosis occurs as a result of increased amounts of HCO_3^- in the ECF. Respiratory acidosis is caused by hypoventilation and decreased excretion of volatile acid (CO_2), whereas respiratory alkalosis is caused by hyperventilation and increased excretion of CO_2 .

Acid–base disorders are also classified according to the number of conditions causing the disorder. When only one primary acid–base abnormality and its compensatory mechanisms occur, the disorder is classified as a *simple acid–base disorder*. When a combination of simple acid–base disturbances occurs, the patient has a mixed (or complex) acid–base disorder. Because secondary physiologic regulatory mechanisms often compensate for the alteration in pH caused by primary disturbances, it is sometimes difficult to differentiate simple from mixed disorders or even a simple disorder from its resulting compensation. One important principle that allows the determination of primary acid–base disturbance is that the compensatory regulatory mechanisms do not completely normalize the pH.

Nomograms, such as the one shown in Fig. 30.6, can help in the diagnosis of the primary disturbance. The nomogram describes the 95% confidence limits of the expected compensatory response

• Fig. 30.6 Acid–base nomogram illustrating the 95% confidence limits for compensatory responses to primary acid–base disorder. (From Cogan MG, Rector Jr FC. Acid-base disorders. In: Brenner BM, Rector Jr FC, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986.)

TABLE 30.5**Expected Compensatory Mechanisms Operating in Primary Acid–Base Disorders**

| Acid–Base Disorder | Primary Event | Compensation | Rate of Compensation |
|------------------------------|--|--|--|
| Metabolic Acidosis | | | |
| Normal anion gap | Decreased HCO_3^- concentration | Decreased PCO_2 | For 1 mEq/L decrease in HCO_3^- concentration, PCO_2 decreases by 1–1.5 mmHg |
| Increased anion gap | Increased acid production Increased acid intake | Decreased PCO_2 | For 1 mEq/L decrease in HCO_3^- concentration, PCO_2 decreases by 1–1.5 mmHg |
| Metabolic Alkalosis | Increased HCO_3^- concentration | Increased PCO_2 | For 1 mEq/L increase in HCO_3^- concentration, PCO_2 increases by 0.5–1 mmHg |
| Respiratory Acidosis | | | |
| Acute (<12–24 h) | Increased PCO_2 | Increased HCO_3^- concentration | For 10 mmHg increase in PCO_2 , HCO_3^- concentration increases by 1 mEq/L |
| Chronic (3–5 days) | Increased PCO_2 | Increased HCO_3^- concentration | For 10 mmHg increase in PCO_2 , HCO_3^- concentration increases by 4 mEq/L |
| Respiratory Alkalosis | | | |
| Acute (<12 h) | Decreased PCO_2 | Decreased HCO_3^- concentration | For 10 mmHg increase in PCO_2 , HCO_3^- concentration increases by 1–3 mEq/L |
| Chronic (1–2 days) | Decreased PCO_2 | Decreased HCO_3^- concentration | For 10 mmHg decrease in PCO_2 , HCO_3^- concentration decreases by 2–5 mEq/L |

 HCO_3^- , Bicarbonate; PCO_2 Modified from Brewer ED. Disorders of acid-base balance. *Pediatr Clin North Am.* 1990;37:429–447.

to a primary abnormality in either PaCO_2 or HCO_3^- concentration. Table 30.5 summarizes the expected respiratory and metabolic compensatory mechanisms for primary acid–base disorders (Brewer, 1990). If the compensation in a given patient differs from that predicted in Fig. 30.6 or Table 30.5, the patient either has not had enough time to compensate for a simple acid–base disturbance or has a mixed acid–base disorder. Furthermore, the complete correction of an acid–base disturbance occurs only when the underlying process responsible for the abnormality has been treated effectively.

For identification of the primary disturbance, the analysis of blood gas values must be considered in light of the patient's history and physical findings and with an understanding of expected compensatory responses. Further laboratory evaluation is indicated if the problem is not immediately obvious or if the response to therapy is not as expected. The evaluation of the acid–base disturbance should always involve efforts to determine the underlying cause of the disturbance, because adequate treatment requires correction of the underlying disorder, if possible.

Transitional Physiology After Birth

As part of a discussion of normal physiology, it is important to understand the in utero environment just before delivery of the newborn and its effects on neonatal acid–base analysis shortly after birth. Hyperventilation of pregnancy is a known phenomenon with corresponding maternal PaCO_2 levels of approximately 31–34 mmHg (Thorp and Rushing, 1999). This relative respiratory alkalosis in the mother is compensated for by a corresponding metabolic acidosis in the mother and therefore in the fetus. As a result, umbilical arterial blood gases have a normal pH range of 7.20–7.28, with a corresponding base deficit ranging from 2.7 ± 2.8 mEq/L to 8.3 ± 4.0 mEq/L (Sykes et al., 1982; Riley and Johnson, 1993).

In other words, a mild metabolic acidosis in the newborn shortly after birth can be expected and explained by normal physiology.

Metabolic Acidosis

Metabolic acidosis is a common problem, particularly in the critically ill newborn. Metabolic acidosis occurs when the drop in pH is caused by the accumulation of acid other than H_2CO_3 in the ECF, resulting in loss of available HCO_3^- , or by the direct loss of HCO_3^- from body fluids. Patients who have metabolic acidosis are divided into those with an elevated anion gap and those with a normal anion gap.

The anion gap reflects the unaccounted acidic anions and certain cations in the ECF. The unmeasured anions normally include the serum proteins, phosphates, sulfates, and organic acids, whereas the unaccounted cations are the serum potassium, calcium, and magnesium ions. Thus in clinical practice, the anion gap is estimated with the formula:

$$\text{Anion Gap} = [\text{NH}_4^+]_{\text{serum}} - ([\text{Cl}^-]_{\text{serum}} + [\text{HCO}_3^-]_{\text{serum}}).$$

The normal range of the serum anion gap in newborns is 8–16 mEq/L, with slightly higher values in very premature newborns. Accumulation of strong acids because of increased intake, increased production, or decreased excretion results in an increased anion gap acidosis, whereas loss of HCO_3^- or accumulation of H^+ results in a normal anion gap acidosis. A decrease in serum potassium, calcium, and magnesium concentrations, an increase in serum protein concentration, or a falsely elevated serum sodium concentration can also result in an increased anion gap in the absence of metabolic acidosis. In clinical practice, although a serum anion gap value greater than 16 mEq/L is highly predictive of the presence of lactic acidosis and a value less than 8 mEq/L is highly predictive of the absence of lactic acidosis, an anion gap value between 8

and 16 mEq/L cannot be used to differentiate between lactic and nonlactic acidosis in the critically ill newborn (Lorenz et al., 1999). Therefore if the anion gap is within this high normal range and lactic acidosis is suggested, measurement of serum lactate is indicated. At present, with the routine availability of measurement of lactic acid from low-volume blood samples by blood gas machines, the determination of the origin of acidosis ("anion gap," i.e., net strong acid gain, or "non-anion gap," i.e., buffer loss–induced acidosis) has become simpler in most clinical presentations of metabolic acidosis.

An increased anion gap metabolic acidosis in the newborn is most commonly caused by lactic acidosis secondary to tissue hypoxia, as seen in asphyxia, hypothermia, severe respiratory distress, sepsis, necrotizing enterocolitis, and other severe neonatal illnesses. Other important but much less common causes of an increased anion gap metabolic acidosis in the neonatal period are inborn errors of metabolism, renal failure, and intake of toxins (Box 30.3). Box 30.4 lists inborn errors of metabolism that can manifest themselves as increased anion gap metabolic acidosis in the newborn period.

In the syndrome of late metabolic acidosis of prematurity, first described in the 1960s, otherwise healthy premature infants at several weeks of age demonstrated mild to moderate increased anion gap acidosis and decreased growth. All the infants were receiving high-protein cow's milk formula and presented with higher

net acid excretion compared with controls. However, this type of late metabolic acidosis is rarely seen nowadays, probably because of the use of special premature infant formulas and changes in regular formulas with decreased casein-to-whey ratios and lower fixed acid loads.

A normal anion gap metabolic acidosis most commonly occurs in the newborn as a result of HCO_3^- loss from the extracellular space through the kidneys or the GI tract. Hyperchloremia develops with the HCO_3^- loss because a proportionate rise in serum chloride concentration must occur to maintain the ionic balance or to correct the volume depletion in the extracellular compartment. The most common cause of normal anion gap metabolic acidosis in the preterm newborn is a mild, developmentally regulated, proximal renal tubular acidosis with renal HCO_3^- wasting. In newborns with this disorder, the serum HCO_3^- concentration usually stabilizes at 14–18 mEq/L in the early postnatal period. The urinary pH is normal once the serum HCO_3^- has stabilized at this level, because the impairment in proximal tubular HCO_3^- reabsorption is not associated with an impaired distal tubular acidification of similar magnitude (Jones and Chesney, 1992). The diagnosis of this temporary cause of acidosis can be established by the recurrence of a urinary alkaline pH when serum HCO_3^- concentration is raised above the threshold after HCO_3^- or acetate supplementation. Even term newborns have a lower renal threshold for HCO_3^- than adults with normal plasma HCO_3^- levels in the range of 17–21 mEq/L. In most infants, plasma HCO_3^- concentration increases to adult levels over the first year as the proximal tubule matures. Other common causes of normal anion gap metabolic acidosis seen in neonatal intensive care units are GI HCO_3^- losses, often caused by increased ileostomy drainage, diuretic treatment with carbonic anhydrase inhibitors, and dilutional acidosis, with rapid expansion of the extracellular space through the use of non- HCO_3^- solutions such as 0.9% sodium chloride in the hypovolemic newborn.

The presence of metabolic acidosis in the newborn may be suspected by the clinical presentation and the history of predisposing conditions, including perinatal depression, respiratory distress, blood or volume loss, sepsis, and congenital heart disease associated with poor systemic perfusion or cyanosis. Metabolic acidosis is confirmed by blood gas measurements. Specific laboratory evaluation of electrolytes, renal function, lactate, and serum and urine amino acids may be undertaken, depending on the diagnosis that is suggested clinically. Fig. 30.7 shows a simple flow diagram outlining an approach to diagnosis of metabolic acidosis in the newborn. It is important to emphasize that newborns might not manifest an increased anion gap in the setting of lactic acidosis (Lorenz et al., 1999). However, the availability of lactic acid measurement along with the blood gas measurements in today's intensive care units aids in the rapid determination of the type of the lactic acidosis.

The morbidity and mortality associated with metabolic acidosis depend on the underlying pathologic process, the severity of the acidosis, and the responsiveness of the process to clinical management. By far the most important intervention for a newborn with a metabolic acidosis is identification of the pathologic process responsible for the development of acidosis and the taking of measures to correct it. It is important to emphasize that the indiscriminate administration of a base, such as sodium bicarbonate, as supportive therapy for all types of metabolic acidosis is unproven in its efficacy (Aschner and Poland, 2008).

The question facing neonatal providers is how low does the pH need to fall before base administration might be associated with improvement in clinical condition for newborns with metabolic

• BOX 30.3 Common Causes of Metabolic Acidosis

Increased Anion Gap

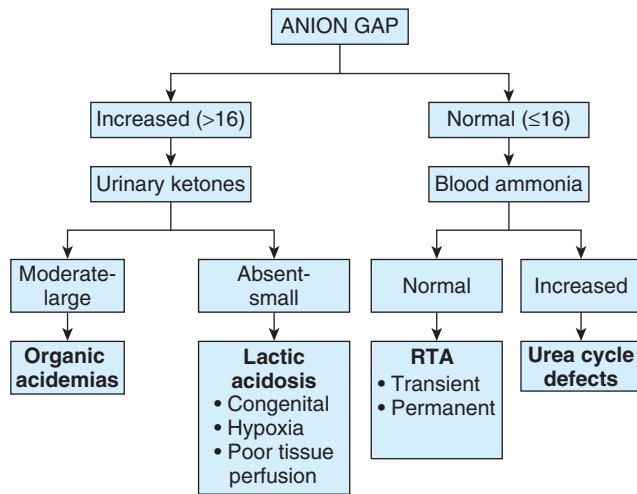

- Lactic acidosis caused by tissue hypoxia
 - Asphyxia, hypothermia, shock
 - Sepsis, respiratory distress syndrome
- Inborn errors of metabolism
 - Congenital lactic acidosis
 - Organic acidosis
- Renal failure
- Late metabolic acidosis
- Toxins (e.g., benzyl alcohol)

Normal Anion Gap

- Renal bicarbonate loss
 - Bicarbonate wasting caused by immaturity
 - Renal tubular acidosis
 - Carbonic anhydrase inhibitors
- Gastrointestinal bicarbonate loss
 - Small bowel drainage: ileostomy, fistula
 - Diarrhea
- Extracellular volume expansion with bicarbonate dilution
- Aldosterone deficiency
- Excessive chloride in intravenous fluids

• BOX 30.4 Inborn Errors of Metabolism Associated With Metabolic Acidosis

- Primary lactic acidosis
- Organic acidemias
- Pyruvate carboxylase deficiency
- Pyruvate hydroxylase deficiency
- Galactosemia
- Hereditary fructose intolerance
- Type I glycogen storage disease

• **Fig. 30.7** Diagnostic Approach of Increased Anion Gap and Normal Anion Gap Metabolic Acidosis in the Newborn. Newborns with lactic acidosis may not have an increased anion gap, and lactate concentration should be directly measured if this is suspected from the history and physical examination. RTA, Renal tubular acidosis. (Modified from Lorenz JM, Kleinman LI, Markarian K, Oliver M, Fernandez J. Serum anion gap in the differential diagnosis of metabolic acidosis in critically ill newborns. *J Pediatr.* 1999;135:751–755)

or severe mixed acidosis. An early study suggested that NaHCO_3 administration to mechanically ventilated preterm and term neonates receiving neuromuscular blockade with an arterial pH of less than 7.25 transiently improved systemic and organ blood flow (Fanconi et al., 1993). However, in a more recent study using more sophisticated hemodynamic evaluation in hemodynamically stable preterm neonates born at 30 weeks' gestation or earlier, myocardial contractility was found to be unaffected by acidosis even at pH values close to 7.00 during the first 2 weeks postnatally. However, and similar to that seen in adults, worsening acidosis in more than 3-day-old preterm neonates was associated with decreased systemic vascular resistance and increased left ventricular output. However, there was no effect of acidosis on vascular resistance and cardiac output during the immediate postnatal period (less than 4 days of postnatal life). It is clear that more data are needed to adequately address this question, especially because of the concern for harm associated with the administration of base. Indeed, a number of studies have shown an association between the use of base and increased mortality and incidence of IVH (Usher, 1967; Simmons et al., 1974; Papile et al., 1978), increased cerebral blood volume regardless of the rate of administration (van Alfen-van der Velden et al., 2006), and decreased intracellular pH with cellular injury (Lipshultz et al., 2003).

If a decision has been made to administer base, the clinician has traditionally had three options: sodium bicarbonate, sodium (or potassium) acetate, and tromethamine. NaHCO_3 is the most widely used buffer in the treatment of metabolic acidosis in the neonatal period. Bicarbonate should not be given if ventilation is inadequate, because its administration results in an increase in PaCO_2 with little to no increase in pH and an increase in intracellular acidosis. Therefore NaHCO_3 should be administered slowly and in diluted form only to newborns with documented metabolic acidosis and adequate alveolar ventilation. Once a blood gas measurement has been obtained, the dose of NaHCO_3 required to fully correct the pH can be estimated with the use of the following formula:

$$\text{Dose of NaHCO}_3 \text{ (mEq)} = \text{Base Deficit (mEq/L)} \times \text{Body Weight (kg)} \times 0.3.$$

NaHCO_3 is confined mostly to the ECF compartment. Although there are controversies regarding the actual bicarbonate space in humans, body weight (kg) \times 0.3 (or 30% of the infant's total body weight) represents its estimated volume of distribution in the neonate. Most clinicians would use half of the calculated total correction dose for initial therapy to avoid overcorrection of metabolic acidosis. Subsequent doses of NaHCO_3 are then based on the results of additional blood gas measurements.

When clinicians are faced with a chronic non-anion gap metabolic acidosis caused by a prematurity-related proximal renal tubular acidosis with bicarbonate wasting, many choose to replace these losses over time. In this instance, either sodium acetate or potassium acetate can be used as an alternative to NaHCO_3 . Sodium acetate is a conjugate base of a weak acid (acetic acid) with a pK_b of 9.25; pK_b is a measure of the strength of a base, which depends on its base dissociation constant. Sodium acetate has been shown in one study to be an effective alternative to NaHCO_3 in correcting this type of acid–base abnormality when added to parenteral nutrition (Peters et al., 1997). The median dosages of acetate used in this randomized controlled trial were 2.6 mmol/kg per day on postnatal day 4 of life and 4.1 mmol/kg per day on postnatal day 8. Neonates randomized to receive acetate had an increased base excess, pH, and PaCO_2 , and they received less bicarbonate boluses compared with control neonates.

Historically, tromethamine has been used as an alternative buffer to sodium bicarbonate, but in recent times its commercial availability has been intermittently limited. The theoretical advantages of tromethamine over NaHCO_3 in the treatment of metabolic acidosis include its more rapid intracellular buffering capability, its ability to lower PaCO_2 levels directly, and the lack of an increase in the sodium load (Schneiderman et al., 1993). Tromethamine lowers PaCO_2 by covalently binding H^+ and thus shifting the equilibrium of the reaction

to the left, resulting in a decrease in the amount of CO_2 and an increase in the amount of HCO_3^- . Tromethamine administration has been associated with the development of acute respiratory depression, most likely secondary to an abrupt decrease in PaCO_2 levels as well as from rapid intracellular correction of acidosis in the cells of the respiratory center (Robertson, 1970). In addition, when large doses of tromethamine are administered, hyponatremia (Seri et al., 1998), hypoglycemia, hyperkalemia, an increase in hemoglobin oxygen affinity, and diuresis followed by oliguria can occur. As tromethamine is hyperosmolar, a slow infusion rate is recommended at a dose calculated from the formula:

$$\text{Dose of Tromethamine (mL)} = \text{Base Deficit (mEq/L)} \times \text{Body Weight (kg)}.$$

Finally, during the correction of metabolic acidosis, regardless of the method chosen, particular attention should be paid to ensuring an appropriate potassium balance. Because potassium moves from the intracellular to the extracellular space in exchange for H^+ when acidosis occurs, the presence of a total body potassium deficit might not be appreciated during metabolic acidosis. Hypokalemia may become evident only as the pH increases and potassium returns to the intracellular space. Furthermore, intracellular acidosis cannot be completely corrected until the potassium stores are restored. Therefore close monitoring of serum electrolyte levels and careful

potassium supplementation are important during the correction of metabolic acidosis in the sick newborn.

Respiratory Acidosis

Respiratory acidosis occurs when a primary increase in PaCO_2 develops secondary to impairments in alveolar ventilation that result in an arterial pH of less than 7.35. Primary respiratory acidosis is a common problem in newborns and causes include hyaline membrane disease, pneumonia owing to infection or aspiration, PDA with pulmonary edema, chronic lung disease, pleural effusion, pneumothorax, and pulmonary hypoplasia. The initial increase in PaCO_2 is buffered by the non- HCO_3^- intracellular buffers without noticeable renal compensation for at least 12–24 hours (see Table 30.5). Renal metabolic compensation reaches its maximum levels within 3–5 days, and its effectiveness in the newborn is influenced mainly by the functional maturity of proximal tubular HCO_3^- transport. Management of respiratory acidosis is directed toward improving alveolar ventilation and treating the underlying disorder. This may include escalation of noninvasive respiratory support, intubation and mechanical ventilation, alternative modes of mechanical ventilation, and/or administration of surfactant.

Metabolic Alkalosis

Metabolic alkalosis is characterized by a primary increase in the extracellular HCO_3^- concentration sufficient to raise the arterial pH above 7.45. In the newborn, metabolic alkalosis occurs when there is a loss of H^+ , a gain of HCO_3^- , or a depletion of the extracellular volume with the loss of more chloride than HCO_3^- . It is important to understand that metabolic alkalosis generated by any of these mechanisms can be maintained only when factors limiting the renal excretion of HCO_3^- are also present.

Metabolic alkalosis can result from a loss of H^+ from the body, from either the GI tract or the kidneys, that induces an equivalent rise in the extracellular HCO_3^- concentration. The most common causes of this type of metabolic alkalosis in the newborn period are continuous nasogastric aspiration, persistent vomiting, and diuretic treatment. Less common causes of H^+ losses are congenital chloride-wasting diarrhea, certain forms of congenital adrenal hyperplasia, hyperaldosteronism, posthypercapnia, and Bartter syndrome.

Metabolic alkalosis can also result from a gain of HCO_3^- , such as occurs during the administration of buffer solutions to the newborn. In the past a metabolic alkalosis was intentionally created when NaHCO_3 or tromethamine was used to maintain an alkaline pH to decrease pulmonary vasoreactivity in infants with persistent pulmonary hypertension, a practice not recommended anymore. Currently, iatrogenic metabolic alkalosis is primarily due to long-term excessive administration of HCO_3^- , lactate, citrate, or acetate in IV fluids and blood products. Because excretion of HCO_3^- is normally not limited in the newborn, metabolic alkalosis resulting from HCO_3^- gain alone should rapidly resolve after administration of HCO_3^- is discontinued. However, if the alkalosis is severe and urine output is limited, inhibition of the enzyme carbonic anhydrase by the administration of acetazolamide may enhance elimination of HCO_3^- .

Metabolic alkalosis can also result from a loss of ECF containing disproportionately more chloride than HCO_3^- , the so-called contraction alkalosis. During the diuretic phase of normal postnatal adaptation, preterm and term newborns retain relatively more HCO_3^- than chloride (Ramiro-Tolentino et al., 1996). The obvious clinical benefits of allowing this physiologic extracellular volume

contraction to occur, especially in the critically ill newborn, clearly outweigh the clinical importance of a mild contraction alkalosis that develops after recovery. No specific treatment is needed in such cases, because with the stabilization of the extracellular volume and renal function after recovery, acid–base balance rapidly returns to normal. Contraction alkalosis due to other causes, however, may require treatment.

As mentioned previously, for metabolic alkalosis to persist, factors limiting the renal excretion of HCO_3^- must be present. The kidneys are usually effective in excreting excess HCO_3^- , but this ability can be limited under certain conditions, such as decreased glomerular filtration rate, increased aldosterone production, and the more common clinical situation of volume contraction–triggered metabolic alkalosis with potassium deficiency. In the last condition, there is a direct stimulation of Na^+ reabsorption coupled with H^+ loss in the proximal tubule and an indirect stimulation of H^+ loss in the distal nephron by the increased activity of the renin–angiotensin–aldosterone system. Contraction alkalosis responds to administration of saline to replace the intravascular volume in conjunction with additional potassium supplementation to account for renal potassium wasting. In the other disorders, however, the primary problem of reduced glomerular filtration rate or elevated aldosterone concentration must be treated for the alkalosis to resolve.

One of the most commonly encountered clinical scenarios of chronic metabolic alkalosis actually occurs in the form of a mixed acid–base disorder in a preterm neonate with chronic lung disease receiving long-term diuretic treatment. Such a newborn initially has a chronic respiratory acidosis that is partially compensated for by renal HCO_3^- retention. Prolonged or aggressive use of diuretics can lead to total body chloride and potassium depletion and contraction of the extracellular volume, thus exacerbating the metabolic alkalosis. By stimulating proximal tubular Na^+ reabsorption and thus H^+ loss, distal tubular H^+ secretion, and renal ammonium production, the diuretic-induced hypokalemia contributes to the severity and maintenance of the metabolic alkalosis. Furthermore, metabolic alkalosis per se worsens hypokalemia, because potassium moves intracellularly to replace hydrogen as the latter shifts into the extracellular space. Although the serum potassium concentration may be decreased, the serum levels in the newborn do not accurately reflect the extent of total body potassium deficit because potassium is primarily an intracellular ion, with approximately 98% of the total body potassium being in the intracellular compartment. In addition, the condition is accompanied by marked hypochloremia and hyponatremia. Hyponatremia occurs in part because sodium shifts into the intracellular space to compensate for the depleted intracellular potassium. If the alkalosis is severe, alkalemia (pH >7.45) can supervene and result in hypoventilation. In this situation, potassium chloride supplementation, and not sodium chloride supplementation, reverses hyponatremia and hypochloremia, corrects hypokalemia and metabolic alkalosis, and increases the effectiveness of diuretic therapy. Because chloride deficiency is the predominant cause of the increased pH, ammonium chloride or arginine chloride also corrects the alkalosis. These agents do not affect the other electrolyte imbalances such as the hypokalemia, so they should not be the only therapy given.

It is important to keep ahead of the potassium losses in infants receiving long-term diuretic therapy rather than to attempt to replace potassium after intracellular depletion has occurred. Because the rate of potassium repletion is limited by the rate at which potassium moves intracellularly, correction of total body potassium deficits can require days to weeks. In addition, there is also a risk

of acute hyperkalemia if serum potassium levels are driven too high during repletion, particularly in newborns in whom an acute respiratory deterioration may occur. Indeed, with worsened respiratory acidosis, potassium will move from the intracellular to the extracellular space. The routine use of potassium chloride supplementation and close monitoring of serum sodium, chloride, and potassium levels are therefore recommended during long-term diuretic therapy to prevent these common iatrogenic problems.

Respiratory Alkalosis

When a primary decrease in PaCO_2 results in an increase in the arterial pH beyond 7.45, respiratory alkalosis develops. The initial hypocapnia is acutely titrated by the intracellular buffers, and metabolic compensation by the kidneys returns the pH toward normal within 1–2 days (see Table 30.5). Respiratory alkalosis is the only simple acid–base disorder in which, at least in adults, the pH can be completely normalized by the compensatory mechanisms (Brewer, 1990). The cause of respiratory alkalosis is hyperventilation, which in the spontaneously breathing newborn is most often caused by fever, sepsis, retained fetal lung fluid, mild aspiration pneumonia, CNS disorders, or urea cycle defects.

In the neonatal intensive care unit, the most common cause of respiratory alkalosis is iatrogenic secondary to hyperventilation of the intubated newborn. Because findings suggest an association between hypocapnia and the development of periventricular leukomalacia (PVL) (Wiswell et al., 1996; Okumura et al., 2001) and chronic lung disease (Garland et al., 1995) in ventilated preterm neonates, avoidance of hyperventilation during resuscitation and mechanical ventilation is of utmost importance in the management of sick preterm newborns. It appears that later onset of hypocarbia is more deleterious in terms of the development of PVL (at 26 hours of age vs. 15 hours of age), with 88% of these patients having poor neurodevelopmental outcome at a median age of 46 months. The current trend of managing preterm neonates with permissive hypercapnia has made the incidence of hypocapnia and respiratory alkalosis much less common. However, it is of note

that *hypercapnia in the transitional period* is associated with increased incidence of periventricular hemorrhage/IVH in very preterm neonates (Kaiser et al., 2006; Fabres et al., 2007). In one study of ventilated preterm neonates, the incidence of hypocapnia was 4%, and hypocapnia was more common in the first 3 days of life (van Kaam et al., 2013). The treatment of neonatal respiratory alkalosis consists in the specific management of the underlying process causing hyperventilation.

Extremely Low-Birth-Weight Infants

ERIC C. EICHENWALD

KEY POINTS

- Although the incidence of preterm birth in the United States has recently fallen, the incidence of extremely low birth weight (ELBW) births remains static at approximately 1% of all births.
- A significant proportion of ELBW survivors continue to suffer from both short-term and long-term complications.
- Current data suggest that many spontaneously breathing, extremely premature infants can be managed successfully with continuous positive airway pressure (CPAP) therapy started in the delivery room.
- Metaanalyses of prospective randomized trials of early CPAP therapy versus intubation and early surfactant treatment show that initial CPAP therapy is associated with a decreased risk of death or bronchopulmonary dysplasia.
- Future research in the care of ELBW infants should focus on identifying best practices so as to narrow the variability in approach to care and with the goal being to prevent long-term disability.

In the past few decades the field of neonatology has experienced significant progress in medical care and improvement in overall patient survival. Advancement in technology, greater use of glucocorticoids prenatally, regionalization of perinatal and high-risk neonatal care, and a more comprehensive understanding of the physiology of the immature infant have all contributed to dramatic increases in survival of very preterm infants. Care of premature infants with birth weights between 1000 and 1500 g has become almost routine in most neonatal intensive care units (NICUs) in the United States.

One of the most significant remaining challenges in neonatology is the care of extremely low birth weight (ELBW) infants (birth weight <1000 g). These infants present one of the greatest medical and ethical challenges to the field. Although they represent a small percentage of overall births and NICU admissions, ELBW infants are often the most critically ill and at the highest risk of death and long-term morbidity of any NICU patient. They also contribute disproportionately to overall hospital days and consume a large percentage of NICU personnel time, effort, and costs of care. Care of these infants is in constant evolution, as a result of new discoveries in both basic and clinical research as well as growing clinical experience. This chapter will review some of the special challenges in and practical aspects of the management of the ELBW infants.

Epidemiology

The percentage of babies born preterm (<37 weeks' gestation) steadily rose in the United States in the early years of the first decade of this century (Behrman and Stith-Butler, 2007), reaching a peak in 2006 at 12.8% of all births. However, more recent data suggest that the overall preterm birth rate has started to decline (Martin et al., 2017). This decline has been driven primarily by a decrease in the birth rate of late preterm infants. The rate of extreme prematurity has remained static, with approximately 1% of births occurring before 28 weeks' gestation. There remains a significant racial disparity in the incidence of extreme preterm birth, with the African-American ELBW birth rate being nearly double that of the Hispanic and non-Hispanic white populations.

Preterm births are associated with the greater availability of assisted reproductive technologies (ARTs) in the United States. Among infants conceived with ARTs in 2012, 34.9% were born preterm (Sunderam, 2015). These technologies result in a higher incidence of preterm infants, in part because of the higher frequency of multiple gestations (Schieve et al., 2002; Sunderam, 2015). In 2012, infants conceived with ART accounted for 19.6% of all multiple-birth infants, representing 19.2% of all twin infants and 29.6% of all triplet or higher-order infants (Sunderam, 2015). Multiple gestations add to the potential morbidity of extremely premature birth because of a higher frequency of intrauterine growth restriction and other medical complications of pregnancy.

Several studies have shown increased survival in the smallest and most premature infants in the past 20 years (Fig. 31.1) (Fanaroff et al., 2007; Stoll et al., 2010, 2015). Improved survival has not been accompanied by a change in the incidence of several major morbidities among survivors at the lowest gestational ages (<26 weeks' gestation) (Stoll et al., 2015) (Table 31.1). However, for infants born at a gestational age (GA) between 26 and 28 weeks, the incidence of severe intracranial hemorrhage, severe retinopathy of prematurity, and periventricular leukomalacia decreased from 2000 to 2012 in the Eunice Kennedy Shriver National Institute of Child Health and Human Development cohort of infants born in institutions participating in the Neonatal Research Network (Stoll et al., 2015). Trends for survival without major in-hospital morbidity in this same cohort suggest an overall improvement, albeit small, for infants born between 25 and 28 weeks' gestation. However, the rates of bronchopulmonary dysplasia (BPD) increased,

likely due to overall improved survival. With the current trends in survival and in-hospital morbidity, the absolute number of extremely premature infants who survive to NICU discharge and in whom a major morbidity is diagnosed in the neonatal period remains high. A significant percentage of these infants continue to have neurodevelopmental and neurosensory disability into childhood (Hack et al., 2005; Marlow et al., 2005; Moore et al., 2012; Adams-Chapman et al., 2015; Linsell et al., 2015).

Perinatal Management

Extremely premature infants born in high-risk perinatal referral centers, especially those with a high volume of such infants, have better short-term outcomes than infants transferred to such centers after birth (Arad et al., 1999; Towers et al., 2000; Chien et al., 2001; Cifuentes et al., 2002; Shah et al., 2005; Bartels et al., 2006; Phibbs et al., 2007; Jensen et al., 2015). Therefore if clinically feasible, the pregnant woman who seems likely to deliver an extremely premature infant should be transferred to a high-risk perinatal center for the expertise in both obstetric and neonatal management. On arrival, the expectant mother should be evaluated for factors that may have predisposed her to preterm labor and should be assessed for the status of the fetal membranes and the presence or absence of chorioamnionitis. In addition, the best

• **Fig. 31.1** Mortality by Gestational Age at Birth in the National Institute of Child Health and Human Development Neonatal Research Network, 1993 to 2012. (From Stoll BJ, Hansen NI, Bell EF, et al. Trends in care practices, morbidity, and mortality of extremely preterm neonates, 1993–2012. *JAMA*. 2015;314:1039–1051.)

obstetric estimate of GA (by the date of the last menstrual period and early ultrasonographic dating, if available), ultrasonographic assessment of fetal size and position, and the presence of other medical or obstetric complications (preeclampsia, placenta previa, abruptio placentae) should be documented. Specimens for recto-vaginal cultures to detect the presence of group B streptococci should also be obtained on admission (Schrag et al., 2002), and treatment with penicillin or ampicillin (or vancomycin for the patient with a severe penicillin allergy) should be initiated until culture results are available. Although unlikely to arrest labor for an extended period, tocolytic agents should be considered for women with preterm uterine contractions without evidence of chorioamnionitis. There is widespread agreement that glucocorticoids should be offered to any woman in whom delivery at 24 to 34 weeks' gestation seems likely. However, a recent systematic review of 17 observational studies concluded that treatment with glucocorticoids at gestational ages less than 24 weeks (22 to 23 weeks) improved survival and should be offered to women who desire active postnatal resuscitation of their newborn (Park et al., 2016).

Premature rupture of the fetal membranes (PROM) occurs in 30%–40% of women who deliver prematurely (Mazor et al., 1998). If PROM is diagnosed without evidence of intrauterine inflammation and/or infection, consideration should be given to the use of prophylactic antibiotic therapy (ampicillin or erythromycin) for the mother. Several studies have shown that such therapy prolongs the latency period, reduces the incidence of chorioamnionitis and endometritis, and improves neonatal outcome (Gibbs and Eschenbach, 1997; Mercer et al., 1997; Mazor et al., 1998; Phupong and Kulmala, 2012). Tocolytic and antibiotic therapy in the setting of PROM may prolong latency by 48 to 72 hours in many extremely preterm pregnancies in which delivery seems likely, allowing the administration of a complete course of glucocorticoids to the mother (Phupong and Kulmala, 2012).

Prenatal Consultation

If possible, all parents who are at risk of delivery of an extremely premature newborn should have a consultation with a neonatologist before the newborn's birth, preferably jointly with a perinatologist caring for the mother (Finer and Barrington, 1998; Cummings et al., 2015). There are several goals of this consultation. First, the neonatologist and perinatologist should inform the parents about

the proposed management of the pregnancy and delivery of the newborn, including a discussion of the advantages of administration of glucocorticoids to the mother, the possible need for cesarean delivery, and delivery room care and resuscitation of the baby. Second, the parents should be informed about the potential risks of both the extent of prematurity and the proposed therapeutic interventions (Tables 31.2–31.3). Third, the neonatologist should investigate the parents' beliefs and attitudes about delivery of an extremely premature newborn and the potential for long-term morbidity. This outline for prenatal consultation is especially important if delivery is expected at the borderline of viability (23 to 24 weeks' gestation) (Cummings et al., 2015).

Data are sparse about the process and results of prenatal consultation with the parents of an extremely preterm newborn. Some studies suggest that significant incongruity exists among the attitudes of obstetricians, nurses, neonatologists, and parents about active delivery room resuscitation and treatment of extremely premature newborns (Streiner et al., 2001; Zupancic et al., 2002). Reuss and Gordon (1995) have shown that the obstetric judgment of fetal

viability was associated with an 18-fold increase in survival for infants with a birth weight less than 750 g, indicating that obstetric attitudes and decisions influence outcome. Obstetricians and nurses tend to overestimate, and parents tend to underestimate, mortality and morbidity in premature infants (Haywood et al., 1994; Doron et al., 1998). Parents report being more in favor of intervening regardless of GA or condition at birth compared with health care professionals (Streiner et al., 2001). In a survey by Ballard et al. (2002), most neonatologists responded that they would respect parents' wishes about resuscitation of a borderline viable newborn. In practice, when parental preferences about active resuscitation are known before delivery of an extremely preterm newborn, neonatologists report that they would alter their management of the newborn in the delivery room accordingly after assessment of the baby after birth (Doron et al., 1998; Arzuaga et al., 2014), indicating the important role for prenatal consultation. However, parental attitudes are likely strongly influenced by physician recommendations about aggressive resuscitation conveyed during the prenatal consultation. This consultation is further complicated by significant variability in physician's opinions about the benefits and burdens of providing intensive care at the borders of viability (De Leeuw et al., 2000; Cummings et al., 2015). Physician attitudes may be influenced by fear of litigation for not actively resuscitating an extremely premature newborn even if parental choices are made clear, as well as local, regional, and national norms (Partridge et al., 2009).

The earliest GA at which resuscitation should be initiated remains controversial among neonatologists (Raju et al., 2014), making firm recommendations for the actual content of prenatal consultation difficult (Kaempf et al., 2006; Cummings et al., 2015). Most studies that describe the outcome of premature infants are based on birth weight rather than GA and thus confound the effects of extremely preterm birth with those of intrauterine growth restriction, but both parents and physicians are usually faced with making decisions on the basis of the anticipated GA at delivery. However, the likelihood of survival without serious sequelae may be influenced by factors other than GA. Using prospectively collected data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network on infants born at 22 to 25 weeks' gestation between 1998 and 2003, Tyson et al. (2008) presented an analysis of some of these factors. In a multivariate analysis, prenatal exposure to glucocorticoids, female sex, singleton gestation, and higher birth weight (in 100-g increments) were each associated with a decrease in the risk of death or of survival with neurodevelopmental impairment. The reduced risk was similar to the risk for infants with an additional week of gestational age. Other data from several studies suggest that in terms of survival and potential for long-term disability, encouragement of active management is appropriate for women expected to deliver at 25 weeks' gestation or later (Piecuch et al., 1997; Wood et al., 2000; Rysavy et al., 2015). More recent studies suggest that proactive perinatal and neonatal management may increase the rate of survival as well as survival without disability in infants born at gestational ages as low as 22 to 23 weeks (Rysavy et al., 2015; Serenius et al., 2015). Even with proactive management, however, the risk of death and severe morbidity is significantly higher before 25 weeks' gestation (El-Metwally et al., 2002; Rysavy et al., 2015; Stoll et al., 2015). Mortality approaches 70%–80% for infants delivered at 23 weeks' gestation, with most survivors having neurodevelopmental sequelae (Vohr et al., 2000; Wood et al., 2000; Rysavy et al., 2015; Stoll et al., 2015). These data should be shared with parents during prenatal consultation, and

TABLE 31.3 Treatment Guidelines for Initial Management of Extremely Low Birth Weight Infants

| Time After Birth | Guideline | Time After Birth | Guideline |
|------------------|--|-------------------------|---|
| Delivery room | Ensure good thermoregulation. “Gentle” ventilation as required. Avoid hyperventilation and hyperoxia. Administer surfactant (if prophylaxis approach). Initiate NCPAP (if early CPAP approach). | First 24 to 48 h | |
| NICU admission | Obtain weight measurement. Administer surfactant within first hour (if rescue approach). Establish vascular access: Peripheral intravenous catheter. Umbilical arterial catheter. Umbilical venous catheter (central, double lumen). Start administration of intravenous fluids as soon as possible with dextrose and amino acid solution. Limit evaporative water losses (humidified incubator). Minimize stimulation. Avoid hyperventilation and hyperoxia. Maintain target oxygen saturations between 88% and 93%. Obtain specimens for complete blood count with differential, blood culture, blood glucose measurement. Give antibiotics as indicated. Give parents information about their child. | Cardiovascular | Monitor blood pressure, give vasopressors as required. Assess newborn for hemodynamically significant patent ductus arteriosus. Obtain echocardiogram as indicated. |
| | | Respiratory | Give additional surfactant doses as indicated. Maintain low tidal volume ventilation. Avoid hyperventilation and hyperoxia. Extubate infant and start use of CPAP as soon as possible. |
| | | Fluid management | Obtain weight every 12 to 24 h. Monitor serum electrolyte, blood glucose, and calcium concentrations every 4 to 8 h. Limit evaporative water losses. Administer skin care. |
| | | Hematologic | Obtain second blood count. Administer transfusion support as indicated. Monitor bilirubin level, give phototherapy as indicated. |
| | | Infection | Consider discontinuing use of antibiotics if blood culture results are negative at 48 h. |
| | | Nutrition | Start administration of amino acid solution, parenteral nutrition. |
| | | Neurologic | Minimize stimulation. Perform screening head ultrasonography. |
| | | Social | Arrange to meet family. |

CPAP, Continuous positive airway pressure; NCPAP, nasal continuous positive airway pressure; NICU, neonatal intensive care unit.

appropriate guidance should be given for decision making about the pregnancy, delivery, and resuscitation of the infant. Some have argued that, because of the risk of long-term disability associated with extreme preterm birth and the difficulty of making an informed decision immediately before delivery, parents should be given the opportunity to discuss these issues during routine prenatal care (Harrison, 2008).

General Principles of Care Specific to Extremely Low Birth Weight Infants

First Hours

The first few hours after admission to the NICU are critical for the ELBW infant, although there are significant variations in practice among hospitals and practitioners. Careful adherence to details in the delivery room and during the first few hours after birth is essential to help avoid some of the immediate and long-term complications often experienced by the ELBW infant. All NICUs should have a consistent approach to the initial care of these fragile newborns in the delivery room and on admission to the NICU. A suggested treatment guideline for the first few hours after birth is presented in Table 31.3, and screening guidelines for common complications are shown in Table 31.4.

Delivery Room

At delivery, strict attention to maintenance of body temperature by means of rapid, gentle drying of the newborn and the use of adequate heat sources is paramount to avoid cold stress. A polyethylene occlusive skin wrap or bag should also be used immediately after delivery to prevent initial evaporative heat losses (Vohra et al., 1999; Reilly et al., 2015). Many ELBW newborns need some form of assisted ventilation immediately after birth because of no or poor respiratory effort. If positive pressure ventilation is required, it should be provided with low inspiratory pressure to prevent overdistention of the lungs, which can result in air leak and other lung injury, and adequate positive end-expiratory pressure (PEEP) to maintain lung volume by use of a flow-inflating bag, or optimally a T-piece resuscitator that allows more consistent delivery of inspiratory pressure and PEEP. Hyperventilation and hyperoxia should also be avoided; oxygen delivery should be titrated over the first few minutes after birth with use of pulse oximetry and time-specific oxygen saturation targets, with a saturation target of 85%–95% at 10 minutes after birth (Wyckoff et al., 2015). The use of room air for resuscitation of these newborns has been proposed to protect them from hyperoxia and damage to the lungs by oxygen free radicals. However, studies have not shown a benefit for short-term outcomes in the use of low initial oxygen concentration (21%–30%)

**TABLE
31.4****Recommended Screening for Common Complications of Extremely Low Birth Weight Infants**

| Complication | Screening |
|--|--|
| IVH | HUS on days 1 to 3; repeat on days 7 to 10. |
| Germinal matrix hemorrhage | Repeat HUS at 30 days. |
| Intraventricular Hemorrhage (IVH) | Repeat HUS every 3 to 7 days until stable or resolved. |
| IVH with ventricular dilation or intraparenchymal bleeding | Repeat HUS every 3 to 7 days until stable or resolved. Consider measurement of resistive indices for progressive ventricular dilatation. |
| Periventricular white matter disease | HUS at day 30; repeat at 36 weeks' postmenstrual age or at discharge. Consider magnetic resonance imaging if HUS findings are equivocal. |
| ROP | Perform ophthalmologic examination at 4 to 6 weeks' postnatal age. Repeat every 2 weeks if no ROP. Repeat weekly if ROP present. Repeat twice weekly for prethreshold disease or rapidly progressive ROP. |
| Audiology screening | Hearing screen no earlier than 34 weeks' postmenstrual age, but before discharge home. |

HUS, Head ultrasonography; IVH, intraventricular hemorrhage; ROP, retinopathy of prematurity.

compared with high oxygen concentration (>65%) in initial resuscitation of preterm newborns (Wyckoff et al., 2015). Since, in most studies, resuscitated babies were in approximately 30% oxygen at the time of stabilization, the International Liaison Committee on Resuscitation currently recommends that initial resuscitation of preterm newborns start with 21%–30% oxygen.

Current data suggest that many spontaneously breathing, extremely premature newborns can be managed successfully with continuous positive airway pressure (CPAP) therapy started in the delivery room (Aly et al., 2005b; Lindner et al., 1999; Morley et al., 2008; SUPPORT Study Group of the Eunice Kennedy Shriver NICHD Neonatal Research Network et al., 2010a). Routine use of CPAP immediately after delivery may obviate the need for intubation in newborns with a GA of 24 weeks or more, and increasing experience with this approach has been shown to improve its success (Aly et al., 2005b; Finer, 2006). According to one report, mechanical ventilation was avoided in approximately one-third of newborns with a GA of 25 weeks or less and in nearly 80% of newborns with a GA of 28 weeks or more with use of this approach (Aly et al., 2005b). Metaanalyses of available randomized trials of CPAP versus prophylactic surfactant indicate that aggressive use of early CPAP therapy in the delivery room is associated with a reduced risk of death or BPD (Rojas-Reyes et al., 2012; Fischer et al., 2013; Schmolzer et al., 2014) and should be considered the preferred mode of initial respiratory support in the spontaneously breathing ELBW newborn after birth.

Some controversy remains as to the best approach for early exogenous surfactant treatment in extremely premature newborns who require intubation in the delivery room or in whom early CPAP therapy fails because of severe respiratory distress. Soll (2009) reported a metaanalysis of eight randomized trials of the use of natural surfactant as prophylaxis versus as a rescue strategy for established respiratory distress syndrome (RDS) in the ELBW newborn. Administration of exogenous surfactant before 15 minutes of age resulted in a reduction in the rates of neonatal death, air leak, and the combined outcome of BPD or death compared with a selective rescue approach. These results suggest that if newborns do require intubation and mechanical ventilation soon after birth,

exogenous surfactant therapy should be administered as soon as possible, preferably in the delivery room.

Admission to the Neonatal Intensive Care Unit

All newborns should be weighed on admission; frequent determination of subsequent weights is a valuable tool in managing fluid and electrolyte balance. In many centers, ELBW infants are initially placed under a radiant warmer for easier access (i.e., for catheter placement). Because of the high transepidermal fluid losses in these newborns, intravenous (IV) solutions containing 5%–10% dextrose should be administered as quickly as possible after admission, and efforts should be made to reduce evaporative water losses by an increase in the relative humidity surrounding the newborn. Fluid requirements increase at lower GAs, owing to both an increased surface area to body weight ratio and skin immaturity. Renal immaturity may also result in large losses of fluid and electrolytes that must be monitored and replaced. Generally, IV fluids administered at a rate of 80 to 100 mL/kg per day will be sufficient to maintain adequate hydration as long as evaporative water losses are minimized. Hydration status over the first few days after birth is assessed by changes in body weight. In addition, serum electrolyte concentrations should be measured every 6 to 8 hours depending on the baby's degree of skin immaturity; blood glucose levels should be monitored as well to assess the baby for glucose intolerance and hyperglycemia. Serum sodium level in the first 2 to 3 days after birth is a reasonable marker of free water status, but urine sodium losses as the glomerular filtration rate increases make these measurements less reliable thereafter.

A plastic heat shield used in concert with the radiant warmer may decrease transepidermal water losses; alternatively, a polyethylene tent with an infusion of warmed humidified air may be used. Several studies suggest that fluid management is improved by use of a humidified incubator instead of a radiant warmer, because of lower water losses (Gaylord et al., 2001; Meyer et al., 2001). Exposure to high humidity may raise the rate of skin colonization with gram-negative organisms, although no increase in the rate of nosocomial infections was observed in several randomized trials

comparing incubators with radiant warmers (Flenady and Woodgate, 2002). However, temperature regulation for the smallest newborns in the first few days may be more difficult in an incubator than in a servo-controlled radiant warmer, because of rapid drops in air temperature as the incubator doors are opened to care for the newborn (Meyer et al., 2001).

Vascular Access

Close monitoring of blood pressure, arterial blood gases, and serum chemistries during the first few days after birth is required in most sick ELBW newborns; therefore it is advantageous to insert an umbilical arterial catheter for reliable access in newborns who require assisted ventilation. Infusion of half-normal saline with 0.5 unit of heparin per milliliter at a low rate (0.5 to 1 mL/hour) is usually enough to maintain catheter patency. Although use of a saline solution rather than a dextrose–water solution in the umbilical arterial line may complicate fluid and electrolyte management, this disadvantage is offset by the advantage of reliable measurement of blood glucose levels, which are frequently required, without disturbing the newborn. Placement of a central umbilical venous catheter (tip at the inferior vena cava–right atrial junction) at the same time as the umbilical arterial catheter is placed also provides the clinician with reliable venous access for infusion of fluids, medications, and blood products. Use of a double-lumen umbilical venous catheter often obviates insertion of a peripheral IV line in the first few days after birth and helps to preserve IV sites and skin integrity.

The length of time that umbilical catheters are left in place differs by hospital. In most centers, use of umbilical lines is generally discontinued after 7 to 10 days because of the potential for catheter-related infection and vascular complications, although it is unusual for arterial access to be needed beyond a few days after birth. Before the umbilical venous catheter is removed, it is advisable to insert a percutaneous central venous catheter with its tip at the junction of the superior or inferior vena cava and the right atrium, dedicated to infusion of parenteral nutrition (see later section on [Nutritional Management](#)). This catheter helps to maintain IV access for nutritional purposes without raising the risk of catheter-related infections and reduces the need to establish and maintain peripheral IV lines (Parellada et al., 1999; Janes et al., 2000). The incidence of complications from percutaneous central catheters, including catheter-related infections, is lower if a limited number of NICU personnel insert and maintain the lines.

Skin Care

The skin of an infant born at 23 to 26 weeks' gestation is extremely immature and is ineffective as an epidermal barrier. Poor epidermal barrier function in the extremely preterm newborn leads to disturbances in temperature regulation and water balance as well as breakdown in skin integrity, which can increase the risk of infection. The stratum corneum, which is responsible for epidermal barrier function, does not become functionally mature in the fetus until approximately 32 weeks' gestation (Rutter, 2000). However, acceleration of the maturation process occurs after birth, so most extremely premature newborns have a mature epidermal barrier by approximately 2 weeks after birth. Until that time, full-thickness skin injury can occur in the ELBW infant from seemingly innocuous causes, such as local pressure from body positioning, removal of adhesives, and prolonged exposure to products containing alcohol or iodine. Such injury can lead to larger transepidermal water

losses, an even greater risk of nosocomial infection, and significant scarring.

Because of these risks, preservation of skin integrity should be incorporated into the care of the extremely preterm newborn (Table 31.5). Limited use of adhesives and extreme care on their removal, frequent repositioning of the newborn to avoid pressure points on the skin, and use of soft bedding or a water mattress are the minimum requirements. Hydrocolloids (e.g., DuoDerm, ConvaTech, Bridgewater, New Jersey, United States) applied to the baby in areas where adhesive tape may come in prolonged contact with the skin (i.e., umbilical catheter or endotracheal tube fixation) to prevent the direct application of tape to the baby may be useful, because it is more easily removed than standard adhesive tape. Polyurethane adhesive dressings (Tegaderm, 3M, St. Paul, Minnesota, United States) or hydrogels (Vigilon, Bard Medical, Covington, Georgia, United States) may also be used to protect areas of skin friction and superficial wounds.

Prophylactic application of preservative-free emollient ointments (Aquaphor, Beiersdorf, Hamburg, Germany) to protect the skin of the ELBW infant has been studied (Lane and Drost, 1993; Nopper et al., 1996; Edwards et al., 2004). Several small

TABLE 31.5 Practical Guidelines for Skin Care of Extremely Low Birth Weight Infants

| Interventions | Guidelines |
|-----------------------|--|
| Adhesive application | <p>Increase adhesive tack by application to dry, clean skin surface.</p> <p>Avoid use of alcohol for skin cleansing.</p> <p>Use smallest amount of tape possible.</p> <p>Use a hydrocolloid or pectin-based layer on the skin before application of heavy adhesive.</p> <p>Avoid use of adhesive over areas of skin breakdown.</p> <p>Avoid use of adhesive bonding agents (e.g., benzoin).</p> <p>Use hydrophilic gel or pectin-based adhesives preferentially.</p> |
| Adhesive removal | <p>Avoid use of adhesive removers and solvents.</p> <p>Use a warm, wet cotton ball to periodically saturate hydrogel adhesives (avoid overdrying and oversaturation).</p> <p>Facilitate removal of adhesive with mineral oil, petrolatum, and emollients if reapplication is not necessary.</p> |
| Emollient application | <p>Infants born at <27 weeks' gestation may benefit from emollient use.</p> <p>Avoid use of multidose containers (e.g., large jars).</p> <p>Use nonperfumed, nonirritating hydrophilic emollients.</p> <p>Recognize potential for emollients to interfere with adhesive and conductive properties of monitoring devices.</p> |
| Emollient removal | <p>Wipe off gently with a soft cloth or gauze if site is contaminated.</p> <p>Avoid repeated attempts to thoroughly cleanse the skin (undesired friction effect).</p> <p>Remove emollients before attaching thermistors or other monitoring devices.</p> |

Data from Hoath S, Narendran V. Adhesives and emollients in the preterm infant. *Semin Neonatol*. 2000;5:289–296.

studies demonstrated smaller transepidermal water losses, improved skin condition, and lower risk of suspected or proven nosocomial infection with prophylactic application of emollient ointments. However, one report documented an increase in the rate of systemic yeast infections in a single NICU coincident with a change to use of prophylactic emollients in ELBW infants, who returned to the baseline after such use was discontinued (Campbell et al., 2000). In the largest study to date, infants randomized to receive prophylactic emollient had better skin integrity during the first month after birth but had a higher rate of nosocomial bacterial infection compared with a control group with no emollient use (Edwards et al., 2004). Given these concerns, routine use of prophylactic emollients is not recommended; however, selective use in ELBW infants at risk of significant skin breakdown may be effective as an adjunct to other types of local skin care already described.

Mechanical Ventilation and Noninvasive Respiratory Support

A high percentage of ELBW infants require some level of assisted ventilation to survive. Data from animal models of RDS indicate that positive pressure ventilation with large tidal volumes damages pulmonary capillary endothelium, alveolar and airway epithelium, and basement membranes (Dreyfuss, 1998). This mechanical damage results in leakage of fluid, protein, and blood into the airways, alveoli, and interstitial spaces, leading to inhibition of surfactant activity and further damage to the lungs. As such, the use of CPAP as a first-line method of respiratory support to avoid mechanical ventilation for ELBW infants has increased in the past several years (Schmolzer, 2014). In infants who do require mechanical ventilation, data suggest that a ventilator strategy that avoids large changes in tidal volume may reduce ventilator-induced lung injury in ELBW infants, an important management goal. The optimal mode, timing, and application of ventilatory support used in the initial management of the ELBW infant to meet this goal remain controversial. However, the objectives of all strategies of assisted ventilation in the ELBW infant should be similar and are (1) to provide the lowest level of ventilatory support possible that will both support adequate oxygenation and ventilation and prevent atelectasis and (2) to try to reduce acute and chronic lung injury secondary to barotrauma, volutrauma, and oxygen toxicity (Clark et al., 2000; Berger et al., 2013; Committee on Fetus and Newborn, 2014).

Noninvasive Ventilation

In a classic study comparing the incidence of BPD between NICUs, Avery et al. (1987) reported that the NICU with the lowest incidence used CPAP more frequently and more aggressively than the other NICUs. Van Marter et al. (2000) confirmed these observations.

Theoretically, early CPAP protects the immature lung from injury caused by positive pressure tidal breaths, by preserving surfactant function, increasing alveolar volume and functional residual capacity, enhancing alveolar stability, and improving ventilation-perfusion matching. It may also stimulate the growth of the immature lung. Most NICUs now use CPAP (delivered via nasal prongs at 5 to 8 cmH₂O) as the initial mode of assisted ventilation for spontaneously breathing ELBW infants, starting in the delivery room (Lindner et al., 1999; Rojas-Reyes et al., 2012; Fischer et al., 2013). CPAP used this way has been reported

in retrospective studies to decrease the need for mechanical ventilation (Poets and Sens, 1996; Gittermann et al., 1997), the need for surfactant treatment, and the incidence of BPD (Lindner et al., 1999; Aly, 2001; de Klerk and de Klerk, 2001; Aly et al., 2005b). In one prospective study (Morley et al., 2008), infants with a GA of 25 to 28 weeks who were breathing spontaneously but required ventilatory assistance at 5 minutes after birth were randomly assigned to treatment with nasal CPAP or intubation and mechanical ventilation. In the infants assigned to receive CPAP, 56% did not require intubation, and surfactant use was halved. Although respiratory outcomes at 36 weeks' postmenstrual age were equivalent in the two study groups, a greater number of infants who were assigned to initial treatment with CPAP had pneumothorax (9% versus 3%). However, as noted already, metaanalyses of prospective randomized trials of early CPAP therapy versus intubation and early surfactant treatment show that initial CPAP therapy was associated with a decreased risk of death or BPD, with the number needed to treat to prevent a case of death or BPD ranging from 25 to 35 (Rojas-Reyes et al., 2012; Fischer et al., 2013). Alternatively, CPAP may be used after prophylactic or rescue surfactant therapy is given during a brief period of intubation and positive pressure ventilation (INSURE [intubate, surfactant, extubate] technique) (Verder et al., 1999; Booth et al., 2006; Dunn et al., 2011). Observational studies of this approach show that approximately one-fourth of infants born before 27 weeks' gestation do not require a subsequent course of mechanical ventilation and are less likely to develop BPD (Dani et al., 2004; Booth et al., 2006). In randomized trials of the INSURE technique versus more prolonged mechanical ventilation after surfactant administration in infants with RDS, the INSURE approach was associated with a reduced need for mechanical ventilation and reduced need for supplemental oxygen at 28 days (Polin et al., 2014). Alternative surfactant delivery methods, including instillation into the pharynx, aerosolized surfactant, or delivery through a thin endotracheal catheter to prevent the need for intubation with an endotracheal tube, are currently under investigation (Kribs and Hummler, 2016).

CPAP can be delivered by a conventional mechanical ventilator with continuous flow, a variable-flow device that adjusts flow through the respiratory cycle, or "bubble" CPAP, in which a tube is immersed in water to the desired depth to generate CPAP, with continuous gas flow bubbling through the immersed tube. Animal data suggest that bubble CPAP increases lung volume and improves gas exchange better than conventional CPAP (Pillow et al., 2007), perhaps secondary to effects of the higher intranasal pressures generated by the bubbling water (Kahn et al., 2008). Other data suggest that work of breathing and thoracoabdominal asynchrony may be lessened with variable-flow devices (Liptsen et al., 2005). Whether these differences are clinically relevant remains to be elucidated.

Many units have started to use a high-flow nasal cannula (HFNC) as an alternative to conventional CPAP devices. HFNC therapy usually refers to the delivery of blended, heated, and humidified oxygen at flows greater than 1 L per minute via small binasal prongs. Reported advantages of HFNC therapy include ease of use and a lower incidence of nasal breakdown compared with conventional CPAP therapy (Manley and Owen, 2016). Potential disadvantages include variable distending pressure delivery (both low and high), and some studies have shown a longer duration of respiratory support with HFNC therapy compared with CPAP therapy. Randomized trials to date comparing HFNC therapy with CPAP therapy as either initial or postextubation support in

extremely preterm infants are limited but suggest that HFNC therapy may be an acceptable alternative to CPAP therapy in some infants, particularly those with a GA of 26 weeks or more (Cummings and Polin, 2016; Owen and Manley, 2016).

Conventional Mechanical Ventilation

Many different modes of conventional mechanical ventilation are available to clinicians in the NICU for the respiratory management of the ELBW infant requiring mechanical ventilation. All advanced modes of mechanical ventilation for newborns include some version of synchronized intermittent mandatory ventilation (SIMV). In the premature infant, SIMV, in which the inspiratory cycle is synchronized with the patient's own effort, is better than conventional intermittent mandatory ventilation in terms of oxygenation, ventilation, work of breathing, and blood pressure variability (Cleary et al., 1995; Hummler et al., 1996; Jarreau et al., 1996). However, technologic limitations in the ability of some ventilators to synchronize breaths generated by very weak inspiratory efforts may prevent the use of SIMV in the smallest infants. With advancement in ventilator design, other modes of patient-triggered ventilation, including volume guarantee, assist control, and pressure support, have become available and have supplanted conventional SIMV as first-line ventilatory therapies (Reyes et al., 2006). Volume-targeted strategies generally allow ventilation at lower pressures and better controlled tidal volumes than conventional SIMV and, as such, may be protective to the surfactant-deficient lung. In metaanalyses, volume-targeted compared with pressure-limited ventilator strategies are associated with a lower risk of death or BPD, pneumothorax, hypocarbia, days of ventilation, and the combined outcome of periventricular leukomalacia and grade 3 or 4 intraventricular hemorrhage (IVH) (Wheeler et al., 2010; Peng et al., 2014). Whether these short-term benefits result in long-term improvement in respiratory or neurodevelopmental outcomes remains uncertain (Stefanescu et al., 2015). However, hyperventilation (partial pressure of carbon dioxide [PaCO_2] <35 mmHg) has been associated with a higher risk of the development of BPD (Garland et al., 1995; Van Marter et al., 2000) and neurodevelopmental sequelae in ELBW infants (Wiswell et al., 1996).

In response to this suggestion of worse pulmonary outcome in hyperventilated infants, a strategy of minimal ventilation, or permissive hypercapnia, has been proposed for conventional ventilation in ELBW infants (Ryu et al., 2012). In the largest study to date of this ventilatory strategy, Carlo et al. (2002) randomly assigned 220 infants with birth weights between 501 and 1000 g to receive either minimal ventilation (target $\text{PaCO}_2 >52$ mmHg) or routine ventilation (target $\text{PaCO}_2 <48$ mmHg). No difference in the rate of death, BPD, or other major short-term morbidities was seen between the two groups. Potential risks of a high PaCO_2 include increases in both cerebral perfusion and pulmonary vascular resistance and lower pH. Without clear data to support the benefit and safety of higher levels of hypercapnia, most centers target their conventional ventilatory strategy to maintain PaCO_2 between 45 and 55 mmHg in the first several days of mechanical ventilation in the ELBW infant.

In neonates whose lung disease prevents extubation in the first several days after birth, changes in lung dynamics in the first 1 to 2 weeks often necessitate a change in ventilatory strategy. In the early stages of chronic lung disease, increased airway resistance and decreased lung compliance may require higher mean airway pressures, peak inspiratory pressures, and PEEP and

longer inspiratory time than are usually used in initial ventilatory management. Once the need for more prolonged mechanical ventilation has been established, many centers tolerate higher target PaCO_2 values in an attempt to limit further ventilator-induced lung injury.

High-Frequency Ventilation

Considerable interest has been generated in the past 20 years in the application of high-frequency ventilation (HFV) in newborns who have respiratory failure, because this technique allows ventilation with small tidal volumes. The results of studies using HFV in animal models of RDS have been promising in the prevention of lung injury, but the results of clinical studies of this ventilatory technique have not. Despite many clinical trials, controversy continues to surround the indications for HFV in ELBW infants, whether HFV is more effective than other modes of ventilation for RDS, whether HFV reduces adverse outcomes (specifically BPD), and whether HFV is more likely to have significant long-term complications than conventional mechanical ventilation.

Early trials of HFV before surfactant replacement therapy demonstrated no pulmonary advantage of HFV over conventional mechanical ventilation and suggested an increase in rates of air leak and intracranial abnormalities in HFV-treated infants (The HIFI Study Group, 1989). Later trials in ELBW infants who were treated with surfactant also failed to demonstrate any reduction in the incidence of BPD in the HFV-treated infants (Rettitz-Volk et al., 1998; Thome et al., 1999; Johnson et al., 2002).

A rigorously controlled trial of HFV as the primary mode of assisted ventilation compared with conventional mechanical ventilation was the first to suggest a small advantage from the early use of HFV in reduction in the incidence of BPD or death without an increase in the incidence of short-term complications in ELBW infants. Courtney et al. (2002) compared high-frequency oscillatory ventilation (HFOV) with synchronized intermittent mandatory ventilation in a randomized trial that enrolled 500 ELBW infants. They found a small but significant decrease in the incidence of BPD in survivors, a requirement of fewer doses of exogenous surfactant, and shorter time to successful extubation in the HFOV-treated group. No differences in other complications of prematurity were observed between the two groups. In another study of HFOV versus conventional ventilation, while no differences were seen in the incidence of BPD in the original trial (Johnson et al., 2002), superior lung function at adolescence was observed in individuals who were assigned to receive HFOV (Zivanovic et al., 2014).

These results suggest that, when used in experienced hands according to strict protocol, HFV confers some protection from lung injury in ELBW infants. It remains unclear whether this same advantage is gained when HFV is used in usual clinical circumstances in less experienced centers and whether the incidence of other complications may be affected by the mode of ventilation. Some NICUs with the most experience with HFV use it routinely as the initial mode of ventilation for ELBW infants. Most centers continue to use volume-targeted ventilation with low tidal volumes and reasonable ventilation goals as the initial mode of ventilation for ELBW infants, reserving HFV for infants in whom conventional ventilation and surfactant therapy fail. This latter practice seems advisable, given the potential risks of HFV, including inadvertent lung overdistention, impaired cardiac output, and increased central venous pressure that may lead to intracranial hemorrhage.

Postextubation Continuous Positive Airway Pressure and High-Flow Nasal Cannula Therapy for Respiratory Distress Syndrome and Apnea

CPAP is commonly used in ELBW infants after extubation to stabilize functional residual capacity and reduce the frequency of apneic spells after the lung disease has improved. All ELBW infants should be extubated as soon as they have recovered from acute RDS and should be given a trial of CPAP to protect them from further ventilator-induced lung injury. When used in combination with methylxanthine therapy, CPAP decreases the need for reintubation because of progressive respiratory distress or apnea (Davis et al., 2003). HFNC therapy has been studied as a substitute for conventional CPAP therapy to prevent postextubation failure. Data from these studies suggest that HFNC therapy is similar to CPAP therapy in preventing extubation failure in infants born at more than 26 weeks' gestation and is associated with less nasal trauma (Cummings and Polin, 2016; Manley and Owen, 2016).

Caffeine treatment before extubation has also been shown to lower the incidence of apnea and the need for reintubation in premature infants. Many ELBW infants benefit from prolonged use of CPAP by nasal prongs after extubation, especially those with frequent or severe episodes of apnea and bradycardia resistant to methylxanthine. Some centers currently provide assisted ventilation through nasal prongs (nasal intermittent positive pressure ventilation) to avoid intubation (Kirpalan et al., 2013); this method may be more successful than conventional CPAP therapy in preventing postextubation failure in some infants (Bhandari et al., 2009). However, the smallest and least mature infants may need prolonged mechanical ventilation because of frequent, severe apneic spells that are unresponsive to other therapies.

Adjunctive Therapies to Prevent Bronchopulmonary Dysplasia

Vitamin A Supplementation

ELBW infants have low stores of vitamin A. Because of the role of vitamin A in promoting lung healing, its deficiency has been linked to a higher risk of development of BPD. In a large multicenter trial, vitamin A supplementation (5000 IU given intramuscularly three times per week for 4 weeks) reduced biochemical evidence of vitamin A deficiency and decreased the incidence of BPD by 12% without adverse effects in ELBW infants who required mechanical ventilation or supplemental oxygen at 24 hours of age (Tyson et al., 1999). Given these efficacy data and the apparent safety, many NICUs choose to administer vitamin A supplementation as described previously to all ELBW infants starting at 24 hours after birth. However, widespread acceptance of this therapy has been limited by concerns over the need for thrice weekly intramuscular injections and the associated pain and stress to the infant as well as by chronic medication shortages.

Caffeine

In a prospective, masked, randomized trial involving newborns with a birth weight of 500 to 1250 g, the initiation of treatment with caffeine citrate (20 mg/kg loading dose, followed by 5 mg/kg per day) in the first 10 days after birth decreased the rate of BPD (a secondary outcome) as compared with placebo (36% vs 47%) without adverse effects (Schmidt et al., 2006). The composite primary outcome of death, cerebral palsy, cognitive delay, deafness,

or blindness at 18 to 22 months of age was also reduced in the babies randomized to receive caffeine citrate (Schmidt et al., 2007), although these benefits did not persist at 5 years of age (Schmidt et al., 2012). Earlier (<3 days) compared with later (>3 days) caffeine administration appears to be associated with better outcomes in ELBW infants (Patel et al., 2013). The effect of caffeine on the incidence of BPD may be secondary to less ventilator-induced lung injury in the caffeine-treated infants, because shorter duration of positive pressure ventilation and supplemental oxygen therapy was associated with its use (Schmidt et al., 2006). Whether *prophylactic* use of caffeine for the primary prevention of BPD or to improve neurodevelopmental outcomes should be recommended in all ELBW infants regardless of the need for mechanical ventilation remains unclear and requires further study.

Inhaled Nitric Oxide

Inhaled nitric oxide (iNO) may improve the pulmonary outcome in some very low birth weight (VLBW) infants through mechanisms that are thought to involve decreased pulmonary vascular resistance or improved ventilation-perfusion matching, bronchodilatation, antiinflammatory effects, promotion of lung remodeling in response to injury, or normalized surfactant function. As a rescue therapy for ELBW infants with severe hypoxic respiratory failure, iNO therapy does not improve either pulmonary outcome or survival, and it may be associated with increased mortality or an increased incidence of IVH (Van Meurs et al., 2005). The results of trials of iNO therapy involving premature infants with less severe lung disease who were at risk of BPD are mixed. In the Nitric Oxide for the Prevention of Chronic Lung Disease study, a multicenter trial involving ventilator-dependent infants with a birth weight of 500 to 1250 g, treatment with iNO started at 7 to 14 days and continued for a total of 23 days and increased survival without BPD as compared with placebo (Ballard et al., 2006). In contrast, in a multicenter trial of iNO treatment started before 48 hours of age and continued for 21 days (20 parts per million [ppm] for 3 to 4 days, then weaned to 10 ppm, 5 ppm, and 2 ppm for 7 days each) in infants with a birth weight of 500 to 1250 g who continued to require mechanical ventilation, only iNO-treated infants with a birth weight greater than 1000 g had a pulmonary benefit (Kinsella et al., 2006). Treated infants in this latter study were also less likely to have ultrasonic evidence of brain injury than were control infants. Long-term follow-up from the latter two studies suggests that iNO therapy is safe and may improve long-term pulmonary outcomes (Hibbs et al., 2008; Watson et al., 2009). However, iNO use for the prevention of BPD is not approved by the US Food and Drug Administration, and routine use of iNO for the prevention of BPD should be discouraged until additional studies are available to define clinical benefit, if any, and the dosing and duration of therapy.

Systemic Corticosteroids

Inflammation also plays an important role in the pathogenesis of BPD; therefore pharmacologic doses of systemic corticosteroids have been widely used for prevention and treatment of BPD in ELBW infants. The use of systemic corticosteroids for the prevention or treatment of BPD is one of the best studied pharmacologic interventions in ELBW infants. Several studies have examined early (<7 days of age) administration of corticosteroids, usually dexamethasone, to prevent the development of BPD in infants at risk (Rastogi et al., 1996; Garland et al., 1999; Stark et al., 2001). A metaanalysis of studies in which corticosteroids were used to prevent rather than treat established BPD suggested that early

corticosteroid treatment in ELBW infants results in more rapid extubation and a lower incidence of BPD (Halliday et al., 2002; Doyle et al., 2014a), although no effect on mortality was observed. However, a higher incidence of short-term complications, including hyperglycemia, hypertension, poor growth, and intestinal perforations and bleeding, was observed in the corticosteroid-treated infants (Garland et al., 1999; Stark et al., 2001; Watterberg et al., 2004; Doyle et al., 2014a). More importantly, long-term follow-up data suggest that exposure to corticosteroid for prevention or treatment of BPD raises the risk of neurologic sequelae in treated infants, including poor head growth, cerebral palsy, and developmental impairment (Watterberg et al., 2010; Doyle et al., 2014b).

The apparently higher risk of long-term sequelae without an effect on overall mortality has tempered enthusiasm for systemic corticosteroid treatment to prevent or treat BPD in ELBW infants. A possible role for postnatal administration of corticosteroids in the prevention of BPD in selected infants, such as those exposed to chorioamnionitis, was suggested by a trial of early treatment with hydrocortisone (Watterberg et al., 2004). The risk of impaired neurodevelopment may be lower with hydrocortisone than dexamethasone (Rademaker et al., 2007; Watterberg et al., 2007), and some centers are substituting hydrocortisone for dexamethasone if corticosteroids are used postnatally.

Nutritional Management

Provision of adequate nutrition is central to effective care of ELBW infants. These infants are born with limited nutrient reserves, immature pathways for nutrient absorption and metabolism, and higher nutrient demands. In addition, medical conditions associated with extreme prematurity both alter requirements for and complicate the adequate delivery of nutrients. The goals of nutritional management of the ELBW infant are preservation of endogenous body stores, achievement of postnatal growth similar to intrauterine weight accretion and body composition, and maintenance of normal physiologic and metabolic processes concomitant with minimization of complications and side effects. However, few ELBW infants are able to meet these goals despite the use of central parenteral nutrition and caloric supplementation of enteral feedings. As a result, significant growth failure is commonplace (Berry et al., 1997; Ehrenkranz et al., 1999; Martin et al., 2009), although more recent data suggest that the incidence of severe growth failure may be decreasing with improved nutritional strategies (Griffin et al., 2016).

Enteral Nutrition

Medical problems of ELBW infants sometimes preclude initiation of enteral feedings for several days to weeks. However, the structural and functional integrity of the gastrointestinal tract depends on the provision of enteral feedings. Withholding enteral feedings at birth imposes risks of all the complications of luminal starvation, including mucosal thinning, flattening of the villi, and bacterial translocation. Early initiation (within the first few hours to days after birth) of low volumes of milk (10 to 20 mL/kg per day, preferably with expressed breast milk; trophic feedings, or “gut priming”) has been studied in several small trials in premature newborns (Schanler et al., 1999a; McClure and Newell, 2000). Trophic feedings are not meant to give the newborn significant nutrition but rather are meant to promote continued functional maturation of the gastrointestinal tract. Documented benefits of trophic feedings include higher plasma concentrations of gastrointestinal hormones, a more mature gut motility pattern, lower incidence of cholestasis, increased calcium and phosphorus

absorption, and improved and earlier tolerance of enteral feedings. Trophic feedings have not been associated with a higher risk of necrotizing enterocolitis or other adverse outcomes; therefore there is no clinical advantage to delaying initiation of feedings in the medically stable ELBW infant.

Feeding intolerance, indicated by gastric residuals that exceed 25%–50% of the volume fed, abdominal distention, or microscopic blood in the stool, is common in ELBW infants and may be difficult to differentiate from early stages of necrotizing enterocolitis. Feeding intolerance may preclude the advance of enteral nutrition for days to weeks, complicating nutritional management and prolonging the need for parenteral nutrition. Numerous feeding strategies that are designed to avoid episodes of feeding intolerance have been used in ELBW infants, including slow increase in enteral volume (~10 to 20 mL/kg per day), use of dilute rather than full-strength milk, continuous versus bolus tube feeding, and use of prokinetic agents. None of these feeding strategies have been found to be clearly superior, although bolus feedings may decrease episodes of gastric residuals compared with continuous tube feedings and may allow a more rapid advance to full enteral volumes as well as promote better growth.

Episodes of feeding intolerance also are reduced in ELBW infants fed human milk rather than specialized formulas for premature infants (Schanler et al., 1999b). Other benefits of giving human milk in ELBW infants include a more rapid advance to full enteral volumes and its positive immunologic effects, with an associated reduction in the risk of necrotizing enterocolitis and late-onset sepsis. Data also suggest that neurodevelopmental outcome may be improved in ELBW infants fed expressed breast milk (Vohr et al., 2006). Many NICUs use pasteurized donor human milk to supplement expressed human milk in mothers who are unable to provide enough breast milk to fully feed their infant or have medical or personal reasons for not providing expressed milk. It is unclear whether donor human milk provides benefits similar to those of maternally expressed milk since heat pasteurization of human milk eliminates many of its immunologic properties. Whether it is maternally expressed or provided by donors, human milk must be fortified with protein, calcium, phosphorus, sodium, and other minerals to provide adequate nutrition in the ELBW infant. In addition to commercially available human milk fortifiers, which increase the caloric density to approximately 24 calories per ounce, human milk can be fortified further to higher caloric densities with medium-chain triglycerides, glucose polymers, and added protein.

Premature infants who are fed fortified human milk may grow more slowly than infants fed premature formulas (Schanler et al., 1999b; Quigley et al., 2014), perhaps because of the variability in fat and caloric content of pumped breast milk or changes in the nutrient composition of human milk with fortification that affects fat absorption. Despite the potential for slower growth in infants fed human milk, its use should be strongly encouraged in ELBW infants because of the immunologic and other nutritional benefits. Further research on how best to fortify human milk is necessary to promote the best rate of growth in ELBW infants. In addition, even after recommended enteral dietary intakes are reached, many ELBW infants continue to have a cumulative energy and protein deficit, which in part explains their later growth failure (Ehrenkranz et al., 1999; Embleton et al., 2001; Martin et al., 2009).

Early Parenteral Nutrition

Protein losses in ELBW infants receiving a glucose infusion alone begin immediately after birth and can approach 1.5 g/kg per day

in the first 24 to 72 hours. Fortunately, these losses can be offset by early administration of an amino acid solution, even at low caloric intakes. Several studies have demonstrated the safety of early administration (within 24 hours after birth) of an amino acid solution, with no abnormal elevations of ammonia or blood urea nitrogen levels even in the most immature newborns (Rivera et al., 1993; Van Goudoever et al., 1995). To prevent early protein deficit, ELBW infants should be given a source of parenteral protein as soon as possible after birth. In one study, ELBW infants who received 3 g or more of protein per day at 5 days of age or less were less likely to have a weight below the 10th percentile at 36 weeks' postmenstrual age and suboptimal head growth at 18 months of age when compared with ELBW infants who received less protein supplementation after birth (Poindexter et al., 2006).

In most centers, parenteral nutrition is used exclusively during the first few days after birth and then is gradually reduced as enteral feedings are introduced. Longer duration of parenteral nutrition is associated with the development of a number of complications, including cholestasis, osteopenia, and sepsis. For example, the risk of an episode of late-onset sepsis in premature infants is 22-fold higher if parenteral nutrition is continued for more than 3 weeks compared with 1 week or less (Stoll et al., 2002b).

Management and Prevention of Infection

Bacterial and fungal infections are an important cause of illness and death among ELBW infants. In addition to the immediate morbidity and death, local and systemic inflammation caused by infections may increase the risk of development of other complications of prematurity, including BPD and brain injury. ELBW infants are frequently exposed to perinatal and delivery complications that raise their risk of early-onset infections (<72 hours). The need for prolonged IV access, exposure to parenteral nutrition, and mechanical ventilation also subject the ELBW infant to a high risk of late-onset nosocomial infections (>72 hours). The frequent infections seen in the ELBW population are related to immaturity of both humoral and cellular immunity. In addition to the judicious use of antimicrobial therapy, environmental controls, nursery surveillance, and modulation of the immature immune response have been proposed as possible interventions to prevent infections in extremely premature infant.

Early-Onset Infections

The incidence of early-onset bacterial infections in VLBW infants is approximately 1%–2%, with a mortality of approximately 30%–40% (Stoll et al., 2002a, 2011). The major risk factor for the development of perinatally acquired bacterial infections is PROM with chorioamnionitis, which frequently complicates premature deliveries (Higgins, 2016). However, many extremely premature births may be associated with intrauterine infection before membrane rupture (Goldenberg et al., 2000). In one study, 41% of premature infants with early-onset sepsis were born less than 6 hours after membrane rupture (Stoll et al., 2002a).

Because the clinical signs of perinatally acquired infection are nonspecific, the index of suspicion and the concern about the possibility of intrauterine infection should always be high in the case of premature birth. All ELBW infants, except those delivered for maternal indications with no labor, should be evaluated for infection at birth by means of a complete blood count with differential and blood culture, and empiric antibiotic therapy with ampicillin and an aminoglycoside should be initiated. A white

blood cell count of less than 5000 cells/ μ L, a ratio of immature to total neutrophils greater than 0.2 to 0.3, and neutropenia (absolute neutrophil count less than 1000 cells/ μ L) are all suggestive of infection but may also be seen in infants with other conditions, including maternal preeclampsia and hypertension. The duration of initial antibiotic therapy depends on the results of the blood culture, blood counts, the clinical course, and the perinatal history. If the blood culture is negative for bacterial growth at 48 hours and the newborn has improved clinically, consideration should be given to discontinuation of antibiotic therapy. Prolonged exposure to antibiotic therapy increases the likelihood of colonization with multiple antibiotic-resistant organisms, the development of fungemia, and necrotizing enterocolitis (Cotten et al., 2009); therefore antibiotic therapy should be reserved for infants with documented infection or a very high index of suspicion of infection based on clinical or historical factors.

The distribution of pathogens causing early-onset sepsis in VLBW infants has changed, likely because of increased use of antibiotics in the intrapartum period for prevention of group B streptococcal infections and treatment of preterm PROM (Puopolo and Eichwald, 2010). As the rate of infections from group B streptococci has diminished with intrapartum antibiotic prophylaxis, the proportion of documented infections from gram-negative organisms has risen (Table 31.6; Stoll et al., 2002a, 2011). An additional change in the epidemiologic characteristics of early-onset infections in premature infants, possibly related to increased use of antibiotics in the intrapartum period, is the increased frequency of infections

TABLE 31.6 Distribution of Pathogens Among 84 Cases of Early-Onset Sepsis Occurring in 5447 Infants Born Between September 1, 1998, and August 31, 2000

| Organism | Number of Cases | Percentage of Cases (%) |
|---------------------------------------|-----------------|-------------------------|
| Gram-negative bacteria | 51 | 60.7 |
| <i>Escherichia coli</i> | 37 | 44.0 |
| <i>Haemophilus influenzae</i> | 7 | 8.3 |
| <i>Citrobacter</i> | 2 | 2.4 |
| Other | 5 | 6.0 |
| Gram-positive bacteria | 31 | 36.9 |
| Group B streptococci | 9 | 10.7 |
| Viridans streptococci | 3 | 3.6 |
| Coagulase-negative staphylococci | 9 | 10.7 |
| Other streptococci | 4 | 4.8 |
| <i>Listeria monocytogenes</i> | 2 | 2.4 |
| Other | 4 | 4.8 |
| Fungi: <i>Candida albicans</i> | 2 | 2.4 |
| Total | 84 | 100 |

Data from Stoll B, Hansen N, Fanaroff A, et al. Changes in pathogens causing early onset sepsis in very low birth weight infants. *N Engl J Med.* 2002;347:240–247.

owing to ampicillin-resistant *Escherichia coli* strains in some centers (Joseph et al., 1998; Stoll et al., 2002a; Bizzarro et al., 2008; Stoll et al., 2011). Current recommendations for empiric antibiotic therapy for ELBW infants at risk of early-onset sepsis have not changed, but continued surveillance of the epidemiologic factors and antibiotic resistance patterns of isolates within individual units is warranted. In infants with severe illness that may be caused by sepsis, broadening initial antibiotic coverage to include a third-generation cephalosporin should be considered.

Late-Onset Infections

Nosocomial infection is a common though preventable complication of intensive care of the ELBW infant. The incidence of late-onset sepsis in ELBW infants who survive beyond 3 days of age is 25%–50%, depending on GA and birth weight, with the median age at onset of the first episode approximately 2 weeks (Fanaroff et al., 1998; Stoll et al., 2002b). The overall mortality rate is approximately 20% but may be as high as 80%, depending on the organism causing sepsis. The risk of neurodevelopmental impairment is increased by approximately 1.5-fold in ELBW survivors of nosocomial bloodstream infections (Stoll et al., 2004). Risk factors for the development of late-onset sepsis include prolonged parenteral nutrition and lipid use, the presence of a central venous catheter, longer duration of mechanical ventilation, and delay in initiation of enteral feedings (Stoll et al., 2002b). These practices and procedures are common events that may be unavoidable in the care of ELBW infants. However, large variations have been observed among NICUs in the rate of late-onset infections in premature infants (Brodie et al., 2000; Stoll et al., 2002b), suggesting that individual NICU practices may affect the incidence of nosocomial infections.

The most common cause of late-onset infections in ELBW infants in most US NICUs remains coagulase-negative *Staphylococcus* (CoNS). However, with recent attention to strategies to prevent late-onset infection (see later), the incidence of CoNS infection has fallen, as has the incidence of all-cause late-onset infections in ELBW infants, although significant intrainstitutional variation exists (Bizzarro, 2015). Infection with CoNS is almost never fatal but is associated with significant morbidity, such as prolonged ventilator use and hospital stay (Gray et al., 1995). Other organisms that cause late-onset infections in ELBW infants are associated with a much higher morbidity and mortality. The distribution of pathogens associated with the first episode of late-onset sepsis among 1313 infants in a cohort of VLBW babies over a 2-year period is shown in Table 31.7.

Presenting features of late-onset sepsis include increased apnea, feeding intolerance, abdominal distention, guaiac-positive stools, increased respiratory support, and lethargy and hypotonia (Fanaroff et al., 1998). Because these symptoms are nonspecific, ELBW infants are frequently evaluated for infection and treated with empiric antibiotic therapy. In one study, use of both vancomycin and antifungal therapy was inversely related to birth weight; approximately three-fourths of infants with a birth weight less than 750 g were treated with vancomycin during their hospital stay, and approximately one-third were treated with antifungals (Stoll et al., 2002b). Central catheters should be removed immediately to ensure adequate treatment of infants in whom sepsis is diagnosed, except for that caused by CoNS (Benjamin et al., 2001).

Endotracheal tube colonization with multiple organisms is common in infants who require prolonged mechanical ventilation. In general, such colonization should not be treated with antibiotics unless there is evidence of pneumonia or significant inflammation

TABLE 31.7

Distribution of Pathogens Associated With the First Episode of Late-Onset Sepsis in National Institute of Child Health and Development Neonatal Research Network Institutions, September 1, 1998, Through August 31, 2000

| Organism | Number of Cases | Percentage of Cases |
|----------------------------------|-----------------|---------------------|
| Gram-positive bacteria | 922 | 70.2 |
| Coagulase-negative staphylococci | 629 | 47.9 |
| <i>Staphylococcus aureus</i> | 103 | 7.8 |
| <i>Enterococcus</i> spp. | 43 | 3.3 |
| Group B streptococci | 30 | 2.3 |
| Other | 117 | 8.9 |
| Gram-negative bacteria | 231 | 17.6 |
| <i>Escherichia coli</i> | 64 | 4.9 |
| <i>Klebsiella</i> spp. | 52 | 4.0 |
| <i>Pseudomonas</i> spp. | 35 | 2.7 |
| <i>Enterobacter</i> spp. | 33 | 2.5 |

Data from Stoll B, Hansen N, Fanaroff A, et al. Late-onset sepsis in very low birth weight neonates: experience of the NICHD Neonatal Research Network. *Pediatrics*. 2002;110:285–291.

indicative of tracheitis (Klompas et al., 2014). Prospective surveillance of common isolates and antimicrobial resistance patterns within individual NICUs can help to guide empiric antibiotic therapy in ELBW infants being evaluated and treated for presumed sepsis. However, indiscriminate use of broad-spectrum antibiotics in the absence of true infection can alter antimicrobial resistance patterns (Goldmann et al., 1996), raising the risk of late-onset infections and complicating therapy.

Prevention of Nosocomial Infection

Because of the frequency and potential severity of late-onset sepsis in ELBW infants, several strategies to prevent infection have been proposed. Using these practices as a guideline, Horbar et al. (2001) observed a decrease in the CoNS infection rate from 22% to 16.6% over a 2-year period in VLBW infants in six study NICUs. Many other investigators have confirmed that changes in practice, primarily surrounding the use and care of central venous catheters, can reduce the overall burden of late-onset infections in individual NICUs, as well as in multicenter quality collaboratives (Kilbride et al., 2003; Aly et al., 2005a; Erdei et al., 2015; Piazza et al., 2016). Some NICUs routinely screen ELBW infants by stool or

respiratory secretion cultures for the presence of multiple antibiotic-resistant organisms, which would necessitate isolation (Gregory et al., 2009). Clusters of infections with unusual organisms should prompt surveillance cultures of infants, potential NICU environmental sources, and NICU staff (Foca et al., 2000). Restriction of broad-spectrum antibiotic use by hospital policy or treatment guidelines may limit the local spread of resistant organisms (Goldmann et al., 1996). Strict adherence to hand hygiene before and after every patient contact and avoidance of overcrowding within NICUs also help to decrease the incidence of infection. The use of alcohol-based hand gels at the bedside may improve compliance with hand hygiene (Harbarth et al., 2002; Helder et al., 2012).

In addition to practice and environmental controls, prophylactic use of antibiotics and modulation of the immune response of ELBW infants have been studied as methods to reduce the incidence of late-onset sepsis. Low-dose vancomycin given continuously via hyperalimentation solutions (Spafford et al., 1994; Baier et al., 1998), intermittently via a peripheral vein (Cooke et al., 1997), or vancomycin lock of the central venous catheter (Garland et al., 2005) has been shown to reduce the incidence of CoNS in premature infants at risk. Concern about the emergence of vancomycin-resistant organisms and the low mortality associated with CoNS infections have prevented widespread use of this approach. Prophylactic fluconazole given for 6 weeks lowered the incidence of fungal colonization and invasive disease in ELBW infants without associated complications or the emergence of resistant organisms (Kaufman et al., 2001, 2005; Manzoni et al., 2007). However, in a randomized study of prophylactic fluconazole compared with placebo in infants with a birth weight less than 750 g, while treatment decreased the incidence of invasive candidiasis, the composite outcome of death or invasive candidiasis was not different between the fluconazole-treated group and the placebo-treated group (Benjamin et al., 2014). These results suggest that routine universal fluconazole prophylaxis for ELBW infants is not warranted; however, such an approach might be advisable for NICUs with a high incidence of fungal infections in their ELBW population.

Prophylactic administration of polyclonal IV immunoglobulin (IVIG) to prevent late-onset sepsis has been studied extensively in premature infants. Several trials have shown a decrease in the incidence of documented sepsis by a small but significant amount in premature infants treated with prophylactic IVIG and no effect on mortality or other complications of prematurity (Lacy, 1995; Ohlsson, 2013). The costs associated with this therapy to achieve the small decrease in infection rates, as well as the increased exposure to blood products, have limited its use; it is unclear whether selective prophylactic IVIG treatment of ELBW infants at the highest risk of sepsis is warranted. Development of more targeted polyclonal or monoclonal γ -globulin preparations for specific organisms that cause sepsis in premature newborns may alter the use of IVIG in the future (Lamari et al., 2000; Weisman et al., 2009).

One strategy that has been under investigation for modulation of the immature immune response to help prevent infections in premature infants is treatment with hemopoietic colony-stimulating factors, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor (Modi and Carr, 2000). Most studies of these factors have been conducted in neutropenic, small-for-gestational-age infants or infants delivered by women with preeclampsia. Treatment with granulocyte colony-stimulating factor in neutropenic infants resulted in an increase in neutrophil counts and reduced the incidence of sepsis in one small trial (Kocherlakota and La Gamma, 1998); however,

a more recent randomized placebo-controlled trial in this same population did not show benefit after the first 2 weeks of therapy (Kuhn et al., 2009). Prophylactic granulocyte-macrophage colony-stimulating factor in small-for-gestational-age preterm infants increased neutrophil counts but did not affect the incidence of late-onset sepsis or improve survival compared with placebo. Taken together, these results suggest that modulation of cellular immune deficiency is likely not beneficial in ELBW infants (Carr et al., 2009).

One recent promising strategy for prevention of late-onset infections in preterm infants is supplementation with bovine lactoferrin, a mammalian milk glycoprotein involved in innate immune host defenses. In a randomized trial, bovine lactoferrin-treated VLBW infants had a lower incidence of first-episode late-onset sepsis compared with placebo-treated VLBW infants (Manzoni et al., 2009). Further study is required before routine use of this therapy can be recommended.

Neurosensory Complications

The major neurosensory complications associated with extremely premature birth are IVH, periventricular white matter injury, and retinopathy of prematurity. Although the incidence of severe IVH has fallen, thanks to the increased use of steroids prenatally and to improvements in NICU management, it remains a major cause of brain injury, with consequent increased risk of abnormal neurodevelopment. Pharmacologic approaches to its prevention after birth have generally been unsuccessful. Prophylactic indomethacin reduces the incidence of severe IVH but does not improve long-term neurodevelopment (Schmidt et al., 2001).

Periventricular white matter injury is the predominant form of brain injury in extremely preterm infants and correlates strongly with the development of cerebral palsy. Its pathogenesis is poorly understood, and no specific neuroprotective strategy is known. In some infants, cerebral blood flow and oxygen delivery measured with near-infrared spectroscopy vary during variations of blood pressure considered to be in the normal range, and this lack of autoregulation of cerebral blood flow may lead to ischemic white matter injury (Evans, 2006). Whether aggressive treatment of hypotension in ELBW infants prevents or may lead to subsequent brain injury is uncertain, probably because blood pressure, which is easily measured, does not correlate well with systemic or cerebral blood flow (Fanaroff et al., 2006; Limperopoulos et al., 2007). A higher rate of white matter injury occurs in the setting of maternal or neonatal infection or with elevated levels of proinflammatory cytokines in amniotic fluid or umbilical cord blood, suggesting that inflammation has a role in the pathogenesis (Viscardi et al., 2004). Advanced magnetic resonance imaging techniques in infants with white matter injury show disturbances in cerebral growth, with reduced volume of both gray and white matter (Inder et al., 2005). These observations might serve to explain the motor and cognitive dysfunction often seen in infants with white matter injury.

Retinopathy of prematurity, a vascular proliferative disorder that affects the incompletely vascularized retina of preterm infants, is a major cause of blindness in these children. Severe retinopathy is 18-fold more likely to develop in infants delivered at less than 25 weeks' gestation compared with 28 weeks' gestation (Fanaroff et al., 2007). Periods of hyperoxia owing to exposure to excessive inspired oxygen concentration contribute to the development of retinopathy (Saugstad, 2006); however, the optimal target range of oxygen saturation is not known. Because fetal hemoglobin shifts

the hemoglobin oxygen saturation curve to the left, oxygen saturations greater than 95% may be associated with arterial oxygen tension greater than 80 mmHg, possibly excessive for the ELBW infant. Conversely, oxygen saturation that is too low can increase the risk of injury to the brain or other end organs (Deulofriet et al., 2006).

Adjusting inspired oxygen concentration to target lower oxygen saturations in extremely preterm infants may decrease the rate of severe retinopathy, although it may be associated with other complications, including a higher risk of death. In a prospective observational study, ELBW infants treated in centers with a restrictive approach to oxygen delivery (i.e., saturation alarm limits of 70%–90%) had less retinopathy requiring cryotherapy (6.3% vs 27.7%) than did those in units with a liberal approach (i.e., alarm limits of 88%–98%), and neurodevelopmental outcome at 1 year of age was similar (Tin et al., 2001). In two other studies with historical controls, the incidence of severe retinopathy decreased after oxygen saturation alarm limits were lowered from 87%–97% to 85%–93% for infants born at 28 weeks' gestation and less until they reached 32 weeks' postmenstrual age (Chow et al., 2003; Vanderveen et al., 2006). Recently, different oxygen saturation targets have been tested in masked randomized trials (Askie et al., 2011). These trials compared two different target oxygen saturation ranges (85%–89% compared with 91%–95%) in infants born between 24 and 27 weeks' gestation. In two trials, retinopathy of prematurity occurred less frequently in survivors assigned to the lower oxygen saturation group. However, death before discharge occurred more frequently in the lower oxygen saturation group (SUPPORT Study Group of the Eunice Kennedy Shriver NICHD Neonatal Research Network et al., 2010; BOOST II United Kingdom Collaborative Group; BOOST II Australia Collaborative Group; BOOST II New Zealand Collaborative Group, 2013). In another similarly designed trial, no differences were found in the rates of death or retinopathy of prematurity by assigned oxygen saturation targets, suggesting that the best target range for oxygen saturation remains unclear (Schmidt et al., 2013; Manja, 2015).

Developmental and Parental Care

ELBW infants are particularly vulnerable to the potentially noxious stimuli of the NICU environment, including light, noise, frequent disturbances, and painful procedures. The ELBW infant reacts to the noisy and well-lit environment of many NICUs with greater variability of blood pressure, ventilatory requirements, and oxygen saturation as well as behavioral disorganization, which may have both short-term and long-term effects on outcome (Jacobs et al., 2002). Modification of the NICU environment to limit exposure of ELBW infants to such stresses—by lowering ambient light and reducing noise, clustering caregiving periods and procedures to allow periods of uninterrupted sleep, and using positioning aids to promote containment—is an intuitive part of their care. Newer NICU designs, transitioning from open common rooms to private room settings, may also facilitate a better environment for vulnerable infants and enhance parental involvement. These environmental and developmental interventions in the NICU can improve physiologic stability and some short-term outcomes in preterm infants, including decreased severity of BPD and shorter length of hospital stay. It remains unclear whether individualized, developmentally supportive care or other developmental interventions started in the NICU improve long-term outcome in ELBW infants (Symington et al., 2009).

In addition to environmental modifications, NICUs should promote parental involvement with their infants, even when they are critically ill. Open family presence guidelines and encouragement of parental caregiving when appropriate may help parents to bond with their baby. Many NICUs have embraced a philosophy of family-centered care, in which a stronger bond is forged with the families of NICU patients by encouraging collaboration among family members and care providers in policy and program development, professional education, and aspects of the delivery of care (Dunn et al., 2006). Skin-to-skin (kangaroo) care, in which the infant is placed unclothed on the mother's or father's bare chest, was originally developed in nonindustrialized countries to maintain temperature regulation in premature infants. It is now used in many NICUs to promote parental attachment. Skin-to-skin care may have a positive effect on infant state organization and respiratory patterns, increase the rate of infant weight gain, improve maternal milk production, and have long-term benefits in infant development and parents' perceptions of their babies (Feldman et al., 2002; Cho et al., 2016). Skin-to-skin care can be initiated in ELBW newborns within the first 2 weeks after birth, when they are medically more stable.

Future Directions

This chapter has presented some of the special needs of the ELBW infant. The medical care of the ELBW infant is a complex combination of knowledge of developmental physiology, evidenced-based interventions, and clinical experience. Wide variability in approaches to care of these infants exists among practitioners and NICUs, as does variability in outcomes. Nevertheless, NICUs involved in treating ELBW infants should develop a coherent approach to the medical and ethical aspects of their care. Future research should focus on identifying best practices to narrow the variability in the approach to care and with the goal to prevent long-term disability. In addition, as we gain a greater understanding of genetic influences on drug metabolism, individualized responses, and the risk of complications of prematurity, it is likely that specific therapies will be able to be targeted to the infants at the highest risk. As more of these tiny infants survive, it is the responsibility of neonatologists to stay abreast of clinical improvements and the short-term and long-term consequences of established and newly proposed medical interventions to provide the best care for these vulnerable infants and to keep parents informed and involved.

Late Preterm Infants

SOWMYA S. MOHAN AND LUCKY JAIN

Had he been alive today, Patrick Bouvier Kennedy would have been hailed as a triumph of neonatal care—after all, he was the son of the former United States President, John F. Kennedy and former First Lady Jacqueline B. Kennedy. Born prematurely at 34 weeks gestation, he would have been aptly labeled as a late preterm neonate; however, based on his birth weight (2.1 kg) and gestational age, few would have predicted the outcome he had then, were he born in 2009. But then, in 1963, little was available to the clinician for the management of hyaline membrane disease—no routine use of neonatal ventilators, no device to provide airway positive pressure, no surfactant, and no antenatal steroids. He died two days after his birth; the New York Times obituary said that “the battle for the Kennedy baby was lost because medical science has not advanced far enough.”

(Lucky Jain and David Carlton, Personal Communication, 2009)

KEY POINTS

- Late preterm infants (34 to 37 weeks' gestation) are at risk of complications associated with prematurity. Because of their more mature appearance, there has historically been a lapse in early recognition and management of these issues.
- Mortality rises with the loss of each gestational birth week before 39 weeks.
- Late preterm infants have higher respiratory morbidity and mortality compared with full-term infants.
- Late preterm infants require close monitoring for feeding issues, hypoglycemia, hyperbilirubinemia, infection, and thermoregulation in the postnatal period and until discharge.
- Birth at earlier gestational ages has an impact on health and mortality beyond the neonatal period.

With nearly 4 million live births per year (Hamilton et al., 2015), the United States has one of the highest birth rates among industrialized countries; it also has the stigma of having a disproportionately high prematurity rate. Decades of efforts to reduce preterm births have not affected this formidable problem. In recent years the problem has been highlighted by the rise in births between 34 and 36½ weeks' gestation, a group referred to as *late preterm infants* (Fig. 32.1). Late preterm infants have a checkered history, having been passed off as nothing more than “near-term” infants, yet being feared as the “quick to spiral down” group when they develop respiratory distress or other neonatal complications. As the number of late preterm infants has grown, so has the awareness of their unique set of problems, such

as delayed neonatal transition, wet lung syndrome, hypothermia, hypoglycemia, and hyperbilirubinemia (Fig. 32.2). Although not unique to this population, these complications have sufficient differences in their manifestations and care that this book devotes an entire chapter to the special considerations applicable to the clinical course and management of late preterm infants.

There has been a shift in the distribution of births away from full-term and postterm and toward earlier gestational ages (Davidoff et al., 2006). This shift has resulted in a disproportionately high rate of premature births, with estimates of up to 12.7% of live births being premature (Hamilton et al., 2015)—defined as less than 37 completed weeks' gestation or less than 260 days, counting from the first day of the last menstrual period (Raju, 2006). Within this group of premature babies, up to 75% are classified as late preterm infants (Adamkin, 2009). Although the reasons for such a high number are multifactorial, higher rates of induced deliveries, cesarean births, and efforts to reduce stillbirths may have contributed to the rise in late preterm births.

Late preterm newborns currently account for up to one-third of all neonatal intensive care unit (NICU) admissions (Ananth et al., 2013; Jacob et al., 2016), adding strain to the overburdened system of healthcare delivery, particularly in community hospitals and rural areas. These admissions range from short stays, for problems such as transient tachypnea of the newborn, to more complicated or extended NICU stays for problems such as persistent pulmonary hypertension of the newborn (PPHN). With the average NICU stay costing up to \$3500 per day, the economic impact of caring for the late preterm baby can be significant. For example, in 1996 the state of California alone could have saved \$49.9 million in healthcare costs by preventing nonmedically indicated deliveries between 34 and 37 weeks' gestation (Gilbert et al., 2003). In addition to the expense of the initial hospitalization, the cost of caring for a late preterm baby can also be compounded by the increased incidence of hospital readmissions as shown in Fig. 32.3 (Kuzniewicz et al., 2013) and the long-term care issues related to persistent problems. The effects of the increasing number of late preterm births create a societal burden in lost productivity, as parents take extended leave from work to be with their fragile newborns. More importantly, there may be lasting effects with neurodevelopmental delays extending into early school age. Because a significant proportion of brain growth occurs during the last 6 weeks of gestation (Adams-Chapman, 2006), late preterm infants are vulnerable to neuronal injury and disruption of normal brain development. Whereas more longitudinal studies are needed, preliminary studies show that late preterm infants are more likely to have a diagnosis of developmental delay within the first 3 years of life, require special needs preschool resources, and have more

• **Fig. 32.1** Definitions of Late Preterm and Early Term. (Modified from Engle WA, Kominiarek MA. Late preterm infants, early term infants, and timing of elective deliveries. *Clin Perinatol.* 2008;35:325–341.)

• **Fig. 32.2** Clinical outcomes in near-term infants (35 to 36 $\frac{6}{7}$ weeks) and full-term infants as a percentage of the patients studied. (Modified from Wang ML, Dorer DJ, Fleming MP, Catlin EA. Clinical outcomes of near-term infants. *Pediatrics.* 2004;114:372–376.)

(Modified from Kuzniewicz MW, Parker SJ, Schnake-Mahl A, Escobar GJ. Hospital readmissions and emergency department visits in moderate preterm, late preterm, and early term infants. *Clin Perinatol.* 2013;40:753–775.)

• BOX 32.1 Characteristics of Late Preterm Infants

- Late preterm infants—defined as born at 34 to 36 $\frac{6}{7}$ weeks' gestation
- Physiologically immature with limited compensatory responses to extrauterine environment compared with full-term infants
- Greater risk than full-term infants of death and morbidities such as:
 - Temperature instability
 - Hypoglycemia
 - Respiratory distress
 - Apnea
 - Jaundice
 - Feeding difficulties
 - Dehydration
 - Suspected sepsis

problems with school readiness (Williams et al., 2013; Shah et al., 2016).

Given their large numbers, the overall socioeconomic effects of the late preterm births can be significant. Strategies are required that can reduce the preventable fraction of late preterm births and work toward reducing the morbidity in situations where continuation of the pregnancy is deemed harmful to the fetus or the mother. This chapter explores the pathophysiology of the major morbidities that affect late preterm infants, the unique challenges faced by clinicians in the management of these conditions, and some recent research findings that may help reduce the disease burden and improve outcomes for this unique population.

Definition

Late preterm birth is an accepted term used for infants born between 34 and 36 $\frac{6}{7}$ weeks' gestation (see Fig. 32.1; Raju et al., 2006). This group of infants was initially referred to as *near-term infants*, but the misleading implication of maturity prompted the name change to *late preterm infants* (Box 32.1). This notion is further validated by recent studies showing that full-term infants born at 37 to 38 weeks' gestation have higher morbidity and mortality than those born at 39 weeks' gestation (Madar et al., 1999; Hansen et al., 2008; McIntire and Leveno, 2008; Shapiro-Mendoza et al., 2008); this has prompted the use of *early term* to describe births at 37 to 38 weeks' gestation.

The term *late preterm infant*, and the gestational age limits, were established by a panel of experts convened by the National Institutes of Health and the National Institute of Child Health and Human Development in 2005. While developing these criteria,

• **Fig. 32.4** Distribution of neonatal intensive care unit admissions by gestational age, highlighting the contribution made by late preterm and early preterm infants. Data were obtained from a large consortium of neonatal intensive care units under a common management. (Modified from Clark RH. The epidemiology of respiratory failure in neonates born at an estimated gestational age of 34 weeks or more. *J Perinatol*. 2005;25:251–257.)

the group considered many factors, including the obstetric guidelines that considered 34 weeks to be a maturational milestone. Beyond 34 weeks' gestation, the level of surfactant is generally considered to be adequate, and so antenatal administration of steroids was not routinely offered to mothers with anticipated delivery (Raju et al., 2006) until recent findings from the Antenatal Late Preterm Steroids (ALPS) study were published showing significant decreases in respiratory complications in late preterm infants born to mothers who received betamethasone antenatally (Gyamfi-Bannerman et al., 2016). Unlike the smaller, more typical premature infant, late preterm infants appear mature because they are larger but have a higher incidence of transient tachypnea of the newborn (TTNB) (Wang et al., 2004; McIntire and Leveno, 2008), respiratory distress syndrome (RDS) (Wang et al., 2004; Clark, 2005), PPHN (Roth-Kleiner et al., 2003), respiratory failure, prolonged physiologic jaundice, late neonatal sepsis (Raju, 2006), thermoregulation issues, hypoglycemia, feeding difficulties (Dudell and Jain, 2006; Escobar et al., 2006; Fuchs and Wapner, 2006), and risk of injury to the developing brain, which can lead to neurodevelopmental problems. Altogether, these problems account for a substantially higher number of NICU admissions for late preterm newborns compared with their full-term counterparts (see Figs. 32.2 and 32.4).

Pathophysiology and Clinical Course

Although many of the diseases discussed in this section are not specific or unique to late preterm infants and are covered in other chapters in this book, it is important to understand and recognize them as part of the unique challenge of caring for late preterm newborns.

Respiratory

Several studies have consistently shown that late preterm infants have higher respiratory morbidity and mortality compared with full-term infants. Many late preterm infants develop respiratory

• **Fig. 32.5** Respiratory morbidity in late preterm and early term infants and the impact of the mode of delivery. *CI*, Confidence interval; *ECD*, elective cesarean delivery; *EmCD*, emergency cesarean delivery; *GA*, gestational age; *PVD*, planned vaginal delivery. (Modified from De Luca R, Boulvain M, Irion O, Berner M, Pfister RE. Incidence of early neonatal mortality and morbidity after late-preterm and term cesarean section. *Pediatrics*. 2009;123:e1064–e1071.)

distress soon after birth (defined as sustained distress for more than 2 hours after birth accompanied by grunting, flaring, tachypnea, retractions, or supplemental oxygen requirement), which occurs more often in late preterm infants than in full-term newborns (28.9% vs 4.2%, respectively) (Wang et al., 2004). In addition, within the early term and late preterm groups, infants born at 37 weeks' gestation are fivefold more likely and babies born at 35 weeks' gestation are ninefold more likely to have respiratory distress compared with babies born at 38 to 40 weeks' gestation (Escobar et al., 2006). For each gestational week of age, infants born by elective cesarean delivery tend to do worse (Fig. 32.5). Madar et al.

(1999) found that the incidence of respiratory distress was significantly increased with every week of gestation less than 39 weeks: 30 in 1000 infants born at 34 weeks' gestation, 14 in 1000 infants born at 35 weeks' gestation, and 7.1 in 1000 infants born at 36 weeks' gestation developed respiratory distress. The cause of respiratory distress is diverse and includes transient tachypnea of the newborn, RDS, persistent pulmonary hypertension, and apnea. Not surprisingly, of the affected babies, the incidence of respiratory distress requiring mechanical ventilation corresponded to the degree of prematurity: 3.3% of late preterm infants born at 34 weeks' gestation, 1.7% of late preterm infants born at 35 weeks' gestation, and 0.8% of late preterm infants born at 36 weeks' gestation (Fig. 32.6; McIntire and Leveno, 2008). The gestational age was also correlated with the need for any kind of respiratory support and admission to the NICU, as shown in Fig. 32.7. Late preterm infants can often present with delayed respiratory transition and transient tachypnea, but the course of respiratory distress in this patient population can be unpredictable (Mahoney and Jain 2013). The problem remains that because of their more mature appearance, their initial presentation with respiratory distress may be misleading

• **Fig. 32.6** Percentage of infants born at late preterm gestation who require mechanical ventilation. (Modified from McIntire DD, Leveno KJ. Neonatal mortality and morbidity rates in late preterm births compared with births at term. *Obstet Gynecol.* 2008;111:35–41.)

• **Fig. 32.7** Gestational age and rates of respiratory treatments and admission in a neonatal intensive care unit in a population of 173,058 liveborn infants (2000 to 2009). CPAP, Continuous positive airway pressure; NICU, neonatal intensive care unit. (Modified from Guoyon JB, Iacobelli S, Ferdunus C, Bonsante F. Neonatal problems of late and moderate preterm infants. *Semin Fetal Neonatal Med.* 2012;17:147–152.)

or not recognized, leading to delay in diagnosis and treatment of potentially more serious conditions such as RDS or PPHN.

Whereas respiratory issues often tend to be transient in a vast majority of these neonates, some spiral into severe PPHN and/or hypoxic respiratory failure requiring additional therapies such as extracorporeal membrane oxygenation (ECMO), inhaled nitric oxide therapy, or high-frequency ventilation (Ramachandrapa et al., 2011). Pulmonary hypertension is more likely in preterm infants (born at 34 to 37 weeks' gestation) who develop RDS than in similar infants born at 32 weeks' gestation. Such predisposition is attributed to a developmental increase in the amount of smooth muscle in the walls of pulmonary blood vessels. PPHN is associated with increased pulmonary vascular resistance (PVR) that eventually leads to right-to-left shunting by means of fetal vascular pathways and ventilation-perfusion mismatching (Dudell and Jain, 2006). Management of neonates who develop significant pulmonary hypertension can be challenging, given the self-propagated nature of hypoxia-induced pulmonary vasoconstriction.

A review of the Extracorporeal Life Support Organization Neonatal Registry from 1986 to 2006 by Ramachandrapa and Jain (2011) found that 14.7% of the ECMO patients during that period were late preterm infants and had a mean gestational age of 35.4 weeks. These infants were more likely to require ECMO secondary to hypoxic respiratory failure or RDS instead of aspiration syndromes, which is the primary insult for full-term infants requiring ECMO (Ramachandrapa et al., 2011). In addition, late preterm infants were older at cannulation (likely because most of these infants are asymptomatic at birth (but gradually develop an increasing oxygen requirement with subsequent development of PPHN), had a longer duration of ECMO support, and were more likely to have intraventricular hemorrhage and other neurologic complications than full-term infants. The overall survival rate was significantly lower (74%) for late preterm infants compared with full-term infants (89%) (Ramachandrapa et al., 2011).

Why is it that even in situations in which amniotic fluid testing shows a mature surfactant profile late preterm infants are nevertheless at risk of developing respiratory distress? Part of the answer lies in the delay in clearing fetal lung fluid. Throughout much of gestation, fetal lungs actively secrete fluid into alveolar spaces via a chloride secretory mechanism. This process can be blocked by inhibitors of Na–K–2Cl cotransport. The fluid that accumulates in the developing lung plays a critical role by providing a structural template that prevents the collapse of the developing lung and promotes its growth. At the time of delivery the lung epithelium becomes integral in the process of switching from placental to pulmonary gas exchange (Jain, 1999; Bland, 2001). For effective gas exchange to occur in the lungs, alveolar spaces must be cleared of excess fluid, and pulmonary blood flow must be increased to match ventilation with the perfusion that is occurring. If either the ventilation or the perfusion is inadequate, the infant will have a difficult time transitioning and will develop respiratory distress. In addition, during fetal development, many abnormalities can occur and interfere with the normal production of this lung fluid. Some problems during development include pulmonary artery occlusion, diaphragmatic hernia, and uterine compression of the fetal thorax from chronic leak of amniotic fluid. All these conditions inhibit normal lung development and growth (Jain and Eaton, 2006).

Although a small role in the clearance of this fluid can be attributed to Starling forces and “vaginal squeeze” (Jain, 1999; Bland, 2001), amiloride-sensitive sodium transport by lung epithelial cells through epithelial sodium channels (ENaCs) has emerged as

• **Fig. 32.8** Epithelial sodium (Na) absorption in the fetal lung near birth. Na enters the cell through the apical surface of both alveolar type I (ATI) and alveolar type II (ATII) cells via amiloride-sensitive epithelial Na channels (ENaC), both highly selective channels (HSCs) and nonselective channels (NSCs), and via cyclic nucleotide-gated channels (CNGCs; seen only in ATI cells). Electroneutrality is conserved with chloride movement through cystic fibrosis transmembrane conductance regulator (CFTR) or through chloride channels (CLCs) in ATI and ATII cells, and/or paracellularly through tight junctions. The increase in cell Na concentration stimulates Na-K-ATPase activity on the basolateral aspect of the cell membrane, which drives out three Na⁺ ions in exchange for two K⁺ ions, a process that can be blocked by the cardiac glycoside ouabain. If the net ion movement is from the apical surface to the interstitium, an osmotic gradient is created, which would in turn direct water transport in the same direction, either through aquaporins (AQPS) or by diffusion. (From Mahoney A, Jain L. Respiratory disorders in moderately preterm, late preterm, and early term infants. *Clin Perinatol*. 2013;40:665–678.) Na-K-Pase, sodium-potassium adenosine triphosphatase.

a key event in the transepithelial movement of alveolar fluid (Fig. 32.8; Bland, 2001; Jain et al., 2001). These ENaCs orchestrate the clearing of fluid from the fetal lungs, and disruption of their function has been implicated in several disease processes affecting the newborn, including TTNB and hyaline membrane disease. The late preterm infant is more susceptible to these problems, in part because ENaC expression is developmentally regulated and peak expression in the alveolar epithelium is achieved only at term gestation, which leaves the preterm infant with lower expression of these channels, thus reducing its ability to clear fetal lung fluid after birth (Smith et al., 2000).

High doses of glucocorticoids have been shown to stimulate transcription of ENaCs in several sodium-transporting epithelia and in the lung (Tomashek et al., 2007). In the alveolar epithelia, glucocorticoids were found to induce lung sodium reabsorption in the late-gestation fetal lung (Tomashek et al., 2007). In addition to increasing transcription of sodium channel subunits, steroids increase the number of available channels, by decreasing the rate at which membrane-associated channels are degraded, and increase the activity of existing channels. Glucocorticoids have also been shown to enhance the responsiveness of the lungs to β -adrenergic agents and thyroid hormones (Venkatesh and Katzberg, 1997).

In addition to problems with lung fluid clearance, several other factors may contribute to the overall burden of respiratory morbidity (Morrison et al., 1995; Levine et al., 2001; Roth-Kleiner et al., 2003; Kolas et al., 2006; Villar et al., 2007; Hansen et al., 2008). Given the shortcomings clinicians face in accurate estimation of gestational age, elective induction and cesarean delivery may have increased the burden of iatrogenic prematurity. In an attempt to minimize the occurrence of iatrogenic RDS in light of the increasing frequency of elective cesarean deliveries—commonly performed between 37 and 40 weeks' gestation (Hales et al., 1993)—fetal lung maturity testing was recommended before elective cesarean

deliveries. Because of the risks and complications associated with amniocentesis, this testing is done infrequently (Dudell and Jain, 2006), especially in light of recent studies showing that even late preterm infants and some early term infants born by cesarean delivery before the onset of labor have respiratory distress despite having mature surfactant profiles. This finding prompted the American College of Obstetrics and Gynecologists (ACOG) (2013) to recommend scheduling elective cesarean deliveries at 39 weeks' gestation or later or waiting for the onset of spontaneous labor. The notable exceptions to this recommendation were the medically indicated early deliveries. In 2013, in an effort to balance the well-established risks of late preterm births with the maternal, fetal, and placental complications associated with some pregnancies (i.e., placenta previa, multiple gestations, preeclampsia, etc.), the ACOG Committee on Obstetric Practice published a committee opinion on the suggested timing for delivery of these complicated pregnancies. For all these medically indicated late preterm deliveries, the ACOG Committee on Obstetric Practice recognized the need to individualize the timing of the delivery to balance maternal and newborn risks of late preterm birth versus continuation of the pregnancy (American College of Obstetricians and Gynecologists Committee on Obstetric Practice and Society for Maternal-Fetal Medicine, 2013). Unfortunately, factors related to the convenience of scheduled elective cesarean deliveries for both families and providers will continue to influence the timing of some elective cesarean deliveries (Dudell and Jain, 2006).

Some studies have shown that the overall morbidities in late preterm infants increase significantly for each week of in utero development lost before 38 weeks' gestation (Shapiro-Mendoza et al., 2008). Since one of the most significant morbidities is the higher risk of respiratory distress in infants born before 37 weeks' gestation, the findings of the recent multicenter randomized trial using antenatal betamethasone antenatally for women at risk of

late preterm delivery (ALPS study) warrant potential changes in the antenatal management of pregnancy during the late preterm gestation if delivery is imminent. This study showed that antenatal administration of betamethasone to women at risk of late preterm delivery (Table 32.1) decreased the need for substantial respiratory

TABLE 32.1 Characteristics at the Baseline of Women Enrolled in the Antenatal Late Preterm Steroid (ALPS) Study

| Characteristic | Betamethasone (n = 1429) | Placebo (n = 1402) |
|--|-----------------------------|-----------------------|
| Indication for Trial Entry | | |
| Preterm labor with intact membranes | 400 (28.0%) | 392 (28.0%) |
| Ruptured membranes | 316 (22.1%) | 304 (21.7%) |
| Expected delivery for gestational hypertension or preeclampsia | 370 (25.9%) | 385 (27.5%) |
| Expected delivery for fetal growth restriction | 46 (3.2%) | 48 (3.4%) |
| Expected delivery for oligohydramnios | 50 (3.5%) | 42 (3.0%) |
| Expected delivery for other indication | 247 (17.3%) | 231 (16.5%) |
| Gestational Age at Trial Entry | | |
| ≤34½ weeks | 369 (25.8%) | 399 (28.5%) |
| 35 to 35½ weeks | 571 (40.0%) | 532 (37.9%) |
| ≥36 weeks | 489 (34.2%) | 471 (33.6%) |
| Mean (±SD) maternal age (years) | 28.6±6.3 | 27.8±6.1 |
| Race or Ethnic Group^a | | |
| Black | 376 (26.3%) | 381 (27.2%) |
| White | 828 (57.9%) | 800 (57.1%) |
| Asian | 57 (4.0%) | 39 (2.8%) |
| Other, unknown, or more than one race | 168 (11.8%) | 182 (13.0%) |
| Hispanic | 405 (28.3%) | 448 (32.0%) |
| Other | | |
| Nulliparous | 457 (32.0%) | 448 (32.0%) |
| Smoking during current pregnancy | 204 (14.3%) | 186 (13.3%) |
| Preeclampsia or gestational hypertension | 433 (30.3%) | 440 (31.4%) |
| Gestational diabetes | 153 (10.7%) | 153 (10.9%) |
| Major congenital anomaly in infant ^b | 11 (0.8%) | 21 (1.5%) |

There were no significant differences between the two groups except for maternal age ($P = .001$) and Hispanic ethnic group ($P = .03$).

^aRace or ethnic group was self-reported. Patients of any race could report Hispanic background.

^bAlthough the presence of a major congenital anomaly was an exclusion criterion, these disorders were not discovered until birth.

support during the first 72 hours after birth, reduced rates of respiratory complications (such as TTNB and bronchopulmonary dysplasia; Table 32.2), and reduced the length of stay in the NICU for late preterm infants delivered by these women (Gyamfi-Bannerman et al., 2016). This study showed a significant reduction (from 14.4% in the placebo group to 11.6% in the betamethasone group; $P = .02$) in the rate of neonatal respiratory complications in late preterm infants delivered to women who had received betamethasone before delivery (Gyamfi-Bannerman et al., 2016).

Gastrointestinal

Nutrition

Feeding problems are one of the primary reasons for delay in the discharge of late preterm infants (Adamkin, 2006). Late preterm infants often have poor coordination of sucking and swallowing because of neuronal immaturity, decreased oromotor tone, and inability to generate adequate intraoral pressures during sucking (Polin et al., 2003; Kinney, 2006; Raju et al., 2006; Engle et al., 2007). Breastfeeding has also been shown to be more difficult for early term or late preterm infants compared with full-term infants (Raju, 2006). These problems can lead to poor caloric intake and dehydration.

These problems are compounded by the variations in practice and nutritional management of these infants, given the paucity of published guidelines. Studies have shown that issues such as hypoglycemia and poor feeding contributed to 27% of all late preterm babies requiring intravenous (IV) fluids, compared with only 5% of their full-term counterparts (Wang et al., 2004). In the face of poor enteral intake, parenteral nutrition may be indicated and can become an important therapy in the care of the late preterm infant but is often delayed in anticipation of a quick recovery (Adamkin, 2006). The challenge then becomes providing adequate nutrition to support growth and also equating the energy expenditure that can occur when the infant faces issues such as hypothermia, sepsis, and respiratory distress, which are often seen in late preterm infants. The energy expenditure of nongrowing low birth weight infants (birth weight less than 2500 g) is 45 to 55 cal/kg per day (Adamkin, 2006). These calories come from several sources in parenteral nutrition, including amino acids and lipids.

Late preterm infants are more adept at handling amino acids, allowing the protein content in parenteral nutrition to be started at 2 g/kg per day. With a protein intake of 2.5 to 3 g/kg per day (with adequate caloric intake), a late preterm infant can achieve weight gain similar to that of a full-term infant fed human milk (Adamkin, 2006). More controversial is the use of IV lipids in late preterm infants. Of the late preterm infants with respiratory distress or disease, there are two subgroups: (1) infants with parenchymal lung disease without increased PVR and (2) those with signs of PPHN or increased PVR (Adamkin, 2006). The concern over the use of lipids in the late preterm infant with lung disease stems from adult studies showing that failure to clear infused lipids has an adverse effect on gas exchange in the lungs (Greene et al., 1976). Contrary to those findings, preterm neonates randomized to different lipid infusion rates did not demonstrate any effect on alveolar–arterial oxygen gradient, arterial blood pH, or oxygenation when randomly assigned to modest doses of lipids (0.6 to 1.4 g/kg per day) in the first week of life (Adamkin, 2006). The other argument for restricted use of lipids in late preterm infants specifically addresses the infants with increased PVR and respiratory disease. The concern is that the high polyunsaturated fatty acid content of lipid emulsions (with excess omega-6 linoleic

TABLE 32.2 Neonatal Respiratory Outcomes in Late Preterm Infants Whose Mothers Received Placebo Versus Betamethasone Before Delivery in the Antenatal Late Preterm Steroid (ALPS) Study

| Outcome | Betamethasone (<i>n</i> = 1427) | Placebo (<i>n</i> = 1400) | Relative Risk (95% CI) | <i>P</i> |

| Composite of respiratory distress syndrome, transient tachypnea of the newborn, or apnea | 198 (13.9%) | 249 (17.8%) | 0.78 (0.66–0.93) | .004 |
| Pulmonary air leak | 5 (0.4%) | 6 (0.4%) | 0.82 (0.25–2.68) | .74 |

Two participants in each group were lost to follow-up for the analysis of neonatal respiratory outcomes.

^aThe primary outcome was defined as any of the following occurrences within 72 hours after birth: CPAP or high-flow nasal cannula therapy for a continuous period of at least 2 hours, supplemental oxygen with a fraction of inspired oxygen of 0.30 or more for a continuous period of at least 4 hours, mechanical ventilation, stillbirth or neonatal death, or the need for ECMO.

^bA severe respiratory complication was defined as any of the following occurrences within 72 hours after birth: CPAP or high-flow nasal cannula therapy for at least 12 hours, supplemental oxygen with a fraction of inspired oxygen of 0.30 or more for at least 24 hours, mechanical ventilation, stillbirth or neonatal death, or the need for ECMO. Except for the duration of CPAP or high-flow nasal cannula therapy and the duration of a fraction of inspired oxygen of 0.30 or more, the criteria for a severe respiratory complication overlap with those of the primary outcome.

^cThe need for resuscitation at birth was evaluated in 1422 infants in the betamethasone group and 1390 in the placebo group.

^dExact confidence limits are provided for the difference between two binomial proportions.¹⁵

acid) feeds into the arachidonic acid pathways, leading to synthesis of prostaglandins and leukotrienes, which can increase vasomotor tone and result in hypoxemia (Adamkin, 2006). Despite the lack of firm evidence for the effects of lipid emulsions in infants with severe respiratory failure with or without pulmonary hypertension, the recommendation is that infants with respiratory disease, but not increased PVR, should receive adequate amounts of lipids to prevent essential fatty acid deficiency; in infants with elements of PPHN, administration of lipids should be avoided during the critical stages of their illness (Adamkin, 2006). Because of these issues and other concerns about parenteral nutrition (e.g., difficulty in optimizing nutrition, the need for IV access and the potential for infiltrates or infection, risk of cholestatic jaundice with prolonged use), enteral feeds should be started as soon as clinically possible while the infant is slowly weaned from parenteral nutrition.

In general, nutritional experts recommend that 34- and 35-week late preterm infants receive nutrient-enriched (22 kcal/oz) milk, whereas older 36- and 37-week late preterm infants with an uncomplicated neonatal course should be fed unfortified milk after discharge (Adamkin, 2006). These nutrient-enriched formulas have a higher protein content (1.9 g/dL versus 1.4 g/dL), increased energy (22 kcal/oz versus 20 kcal/oz), and additional calcium, phosphorous, zinc, trace elements, and vitamins compared with standard formulas (Adamkin, 2006). This enrichment becomes essential to the late preterm infant born at 34 to 35 weeks' gestation or the older group of late preterm infants who had a difficult NICU course, where the goal is to compensate for earlier deprivation of adequate nutrition and allow for somatic and brain growth during the first year. These issues notwithstanding, these nutritional guidelines are not always followed, leading to variability in

nutritional practices by providers. One study showed that although nearly 46% of late preterm infants were discharged home with recommendations for use of formula that contained more than 20 kcal/oz, this practice recommendation had a broad range of followers (4% to 72%) (Adamkin, 2006). The issue becomes more pressing in the late preterm infant with chronic conditions, such as bronchopulmonary dysplasia, that are often associated with growth failure caused by inadequate nutrient intake.

For mothers who choose to breastfeed their late preterm infant, this can often be more challenging compared with nursing a full-term infant. The challenge often lies in initiating and establishing breastfeeding because these infants are sleepier, have less stamina, have more difficulty maintaining body temperature, have problems with latching, sucking, and swallowing, and have more respiratory instability than full-term infants (Adamkin, 2006). Despite these obstacles, mothers should still be encouraged to provide breast milk, given the numerous proven benefits of breast milk. Recent studies have shown that the advantages of breast milk feeding for premature infants might be even greater than those for full-term infants (Adamkin, 2006).

Hypoglycemia

Hypoglycemia is defined as low circulating blood glucose concentrations, but the actual neonatal threshold value is still debated. A physiologic definition (blood glucose concentration <45 mg/dL) was established decades ago, on the basis of abnormal electroencephalograms at glucose levels that were lower than that value (Koh et al., 1988). Hypoglycemia is often missed in late preterm infants, mainly because of the early admission of these infants to the well-baby nursery or the mother's room in an effort to triage the limited number of acute care beds in the NICU and to allow the mother to bond with her new baby (Garg and Devaskar, 2006). However, developmental immaturity is associated with multiple problems, including decreased glycogen stores and feeding difficulties, both of which can lead to hypoglycemia (Box 32.2). Another potential factor in the incidence of hypoglycemia in the late preterm population is the use of steroids antenatally in mothers at risk of late preterm delivery. The ALPS study found that there was an increased incidence of hypoglycemia in the newborns whose mothers had received steroids antenatally compared with the placebo group. Neonatal hypoglycemia was found in 24% of the betamethasone group versus 15% of the placebo group, probably secondary to maternal hyperglycemia because of the steroids (Gyamfi-Bannerman, 2016). Therefore because of the multiple factors previously mentioned, it is not surprising that the incidence of hypoglycemia in preterm infants is threefold greater than that in full-term infants (Wang et al., 2004).

In addition, severe hypoglycemia is a well-known risk factor for neuronal cell death and adverse neurodevelopmental outcomes (Garg and Devaskar, 2006). If hypoglycemia is not recognized and treated in a timely manner with IV fluids or feedings, the infant can develop neurodevelopmental abnormalities because the compensatory mechanisms for protecting the brain from hypoglycemia are not fully developed (Cornblath and Ichord, 2000; Cornblath et al., 2000; Vannucci and Vannucci, 2001; Rozance and Hay, 2006). Early recognition, diagnosis, and treatment of hypoglycemia are therefore crucial to the late preterm infant's long-term outcome. We recommend that institutions develop protocols for routine testing of blood glucose levels in late preterm infants. One can use existing serum glucose screening protocols for infants at high risk of hypoglycemia (i.e., small for gestational age, large for gestational age, infant of a diabetic mother). If none

• BOX 32.2 Causes of Hypoglycemia in the Late Preterm Infant

Transient Hypoglycemia in the Late Preterm Infant

Maternal Conditions

- Glucose infusion in the mother
- Preeclampsia
- Drugs: tocolytic therapy, sympathomimetics
- Infant of diabetic mother

Neonatal Conditions

- Prematurity
- Respiratory distress syndrome
- Twin gestation
- Neonatal sepsis
- Perinatal hypoxia–ischemia
- Temperature instability: hypothermia
- Polycythemia
- Specific glucose transporter deficiency
- Isoimmune thrombocytopenia, Rh incompatibility

Persistent Hypoglycemia in the Late Preterm Infant

Endocrine Disorders

- Pituitary insufficiency
- Cortisol deficiency
- Congenital glucagon deficiency

Inborn Errors of Metabolism

- Carbohydrate metabolism: glycogen storage disease, galactosemia, fructose 1,6-diphosphatase deficiency
- Amino acid metabolism: maple syrup urine disease, propionic acidemia, methylmalonic acidemia hereditary tyrosinemia
- Fatty acid metabolism: acyl coenzyme A dehydrogenase defect, defects in carnitine metabolism, β -oxidation defects
- Defective glucose transport

are available, the following is recommended: glucose checks between 1 and 2 hours after birth, followed by testing before the next three consecutive feeds and then before alternate feedings for the remainder of the first 24 hours. If the blood glucose level is less than 40 to 45 mg/dL, then the hypoglycemia management protocol should be followed.

Hypoglycemia is not a problem in utero, because the fetus receives a steady supply of glucose primarily by maternal transfer through the placenta. Once the baby has been delivered, this constant supply of glucose is abruptly stopped, and the infant has to rely on glucose production primarily via hepatic glycogenolysis and gluconeogenesis (Halamek et al., 1997). After birth, the baby experiences a surge in the levels of catecholamines, glucagon, and corticosteroids, which play a key role in maintaining a euglycemic state. The increase in the levels of catecholamines leads to a surge in glucagon concentration and a decline in circulating insulin concentrations, which both contribute to maintaining a normal serum glucose level. Glucose levels are also affected by the unregulated insulin production by the immature pancreatic β cells (Garg and Devaskar, 2006). As a result, the late preterm newborn can experience significant hypoglycemia secondary to developmentally immature hepatic enzyme systems for gluconeogenesis, glycogenolysis, and hormonal dysregulation (Garg and Devaskar, 2006; Raju et al., 2006; Engle et al., 2007).

The neonatal glucose requirement is 6 to 8 mg/kg per minute, which is higher than that observed in adults (3 mg/kg per minute)

(Bier et al., 1977). This demand for glucose increases if the late preterm infant has coexisting conditions such as sepsis, birth asphyxia, or cold stress (Greisen and Pryds, 1989; Halamek et al., 1997; Halamek and Stevenson, 1998). Treatment options for hypoglycemia in the late preterm infant include establishing early feeds (supplementing them with formula if the quantity of breast milk is insufficient), glucose infusion through IV fluids, hydrocortisone, and glucagon (Garg and Devaskar, 2006). The treatment choice for the late preterm infant is based on the underlying cause of the hypoglycemia. Regardless of the cause of the hypoglycemia, it is important to constantly monitor the glucose levels until they stabilize and the baby is tolerating adequate nutrition.

Hyperbilirubinemia

Hyperbilirubinemia is the most common clinical condition requiring evaluation and treatment in the late preterm newborn and the most common cause for readmission during the first postnatal week of life (Maisels and Kring, 1998; Brown et al., 1999; Bhutani et al., 2004; Escobar et al., 2005). Late preterm infants are more likely than full-term infants to be rehospitalized for jaundice (4.5% vs 1.2% in full-term infants) (Escobar et al., 2005).

In general, neonatal hyperbilirubinemia in late preterm infants is more prevalent, more pronounced, and more protracted than in their full-term counterparts. Newman et al. (1999) showed that infants born at 36 weeks' gestation have an eightfold increase in the risk of developing a total serum bilirubin concentration greater than 20 mg/dL (343 μ mol/L) when compared with those born at 41 weeks' gestation or later. Part of the reason for this increased risk is the immature hepatic metabolic pathways for bilirubin and the overall immaturity of gastrointestinal function and motility. The decreased ability for hepatic uptake and conjugation puts the late preterm infant at increased risk of elevated serum bilirubin levels, and the jaundice then becomes more prolonged, more prevalent, and more severe (Bhutani and Johnson, 2006). In addition, late preterm infants are at increased risk of kernicterus at bilirubin levels equal to or lower than those of full-term infants (Bhutani and Johnson, 2006). Kernicterus is a devastating, chronic, and disabling condition characterized by the tetrad of choreoathetoid cerebral palsy, neural hearing loss, palsy of vertical gaze, and dental enamel hypoplasia (Watchko, 2006).

Whereas the need for universal predischarge bilirubin testing in neonates is debated, it is generally accepted that late preterm infants are at higher risk and should not be included in the same management guidelines as full-term infants. The recommendation from the American Academy of Pediatrics from 2004 for the management of hyperbilirubinemia recommends that all newborns be assessed for their risk of developing hyperbilirubinemia by use of predischarge total serum bilirubin or transcutaneous bilirubin measurements (Kuzniewicz et al., 2009). The effectiveness of this policy was studied by Kuzniewicz et al. (2009), and they concluded that universal bilirubin screening, whether using transcutaneous bilirubin or total serum bilirubin for measurements, was associated with increased identification of newborns needing phototherapy and a significantly lower incidence of severe hyperbilirubinemia.

This finding underscores the need for close monitoring of late preterm infants, particularly breastfed infants whose mothers may not have a proper milk supply before being discharged home. Early discharges should be avoided until proper feeding has been established, and early follow-up should be arranged (Wallenstein and Bhutani, 2013).

Infectious Diseases

Late preterm infants are also more susceptible to infections because of their immunologic immaturity. The timing of the infection categorizes them as congenital (acquired before delivery), early onset (usually acquired during delivery and presenting within the first 72 hours), or late onset (often acquired in the hospital and presents after 72 hours of life). Congenital infections are commonly attributed to rubella virus, cytomegalovirus, herpes simplex virus, and human immunodeficiency virus (HIV) (Benjamin and Stoll, 2006). The severity of the infection and its effect on the late preterm infant depend on the stage of pregnancy at which the maternal infection occurred. With both herpes simplex virus and HIV, maternal–infant transmission is more frequent if a mother has a primary infection at the time of delivery, whereas maternal viral load is the main risk factor for HIV transmission from the mother to the newborn (Benjamin and Stoll, 2006).

Early-onset sepsis is almost always caused by perinatally acquired infections. In most cases the late preterm infant is initially colonized by exposure to various organisms in the maternal genital tract, including group B streptococcus, *Escherichia coli*, and *Candida* species (spp.). Additional risk factors for developing sepsis are prolonged rupture of membranes (more than 18 hours), maternal fever, and chorioamnionitis (Puopolo et al., 2011; Polin and Committee on the Fetus and Newborn, 2012).

The third group—late-onset sepsis—may be caused by perinatally or postnatally acquired organisms but is usually a consequence of nosocomial transmission. The most common organisms are gram-negative rods, but sepsis could be caused by *Staphylococcus aureus*, *Enterobacter* spp., or *Candida* spp. Although the mortality rate is low for late preterm infants, infections increase the risk of complications and often involve longer hospital stays (Benjamin and Stoll, 2006).

In addition, late preterm infants undergo testing for sepsis more often than full-term infants (36.7% vs 12.6%; odds ratio 3.97; 95% confidence interval 1.82–9.21; $P = .00015$) and receive antibiotics more often and for a longer duration (30% receive a 7-day course vs 17% of full-term infants; Wang et al., 2004). Other studies show that the need for a sepsis evaluation increases with decreasing gestational age; 33% were evaluated for possible sepsis at 34 weeks' gestation compared with 12% at 39 weeks' gestation ($P < .01$), of which only 0.4% of infants had culture-proven sepsis (McIntire and Leveno, 2008). This higher frequency of sepsis screening of late preterm newborns (compared with full-term newborns) may be multifactorial. First, records show that one-third of all preterm deliveries occur after prolonged premature rupture of membranes, which can put the newborn at a significantly higher risk of infection. Second, the higher rate of sepsis work-ups in the late preterm baby may be a reflection of a standard protocol used for admissions to the NICU or may be due to their clinical presentation (e.g., respiratory distress, hypothermia, hypoglycemia), which could either be a sign of sepsis or a reflection of the infants' immaturity.

Thermoregulation

Because they are smaller, late preterm infants are susceptible to periods of hypothermia or cold stress. Unfortunately, as for other problems discussed earlier, this may be difficult to assess if the late preterm newborn has been sent to the mother's room or is not closely observed. Usually cold stress will manifest itself as tachypnea or apnea, poor feeding, poor color caused by peripheral vasoconstriction, and metabolic acidosis. Hypothermia and its related consequences can

delay the respiratory transition and exacerbate hypoglycemia; these signs and symptoms may also be misinterpreted as possible sepsis, which then leads to unnecessary interventions and work-ups.

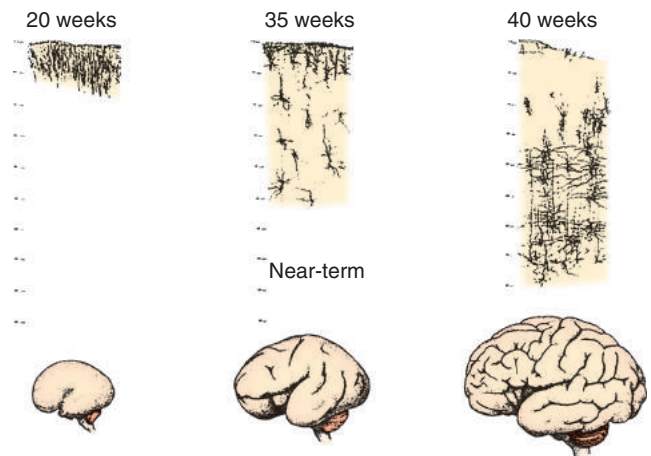

The reason that late preterm infants are more susceptible to temperature instability is because of their physiologic immaturity of thermoregulation, which in turn is dependent on the amount of brown and white adipose tissue and on body surface area (see Chapter 29). Nonshivering thermogenesis is controlled by the hypothalamic ventromedial nucleus through the sympathetic nervous system, which releases the neurotransmitter norepinephrine. The norepinephrine then causes the brown adipose tissue to liberate free fatty acids, which are eventually oxidized and produce heat (see Chapter 29). Late preterm infants have decreased stores of brown adipose tissue and the hormones responsible for brown fat metabolism (i.e., prolactin, norepinephrine, triiodothyronine, and cortisol). The stores of these hormones normally peak at term gestation, and the late preterm infant misses those last few weeks of in utero development. In addition to the decreased stores of hormones leading to thermogenesis, late preterm infants also have problems with hypothermia because of a decreased amount of white adipose tissue, which leads to less insulation and their smaller size. The late preterm infant's relatively smaller size, compared with full-term infants, leads to an increased ratio of surface area to body weight, which results in greater heat loss to the environment (see Chapter 29). Appropriate monitoring and triaging of the late preterm infant who is susceptible to temperature instability can avoid unnecessary morbidity, work-ups, interventions, and prolonged hospitalizations.

Neurodevelopment

During pregnancy, fetal lungs and brain are among the last organs to mature and are therefore more prone to injury. Not surprisingly, even healthy near-term or late preterm infants are at risk of developmental delays through the first 5 years of life (Raju, 2006). During the final few weeks of gestation, many aspects of brain maturity are still in progress. These aspects include maturing oligodendroglia, increasing neuronal arborization and connectivity, maturation of neurotransmitter systems, and continued brain growth that accounts for a 30% increase in brain size during the last few weeks of gestation (Fig. 32.9; Jain and Raju, 2013). At 34 weeks' gestation the brain weighs only 65% of the weight of the brain of a 40-week full-term infant (Billiards et al., 2006; Kinney, 2006). The brain of a late preterm infant is still immature and continues to grow until 2 years of age, when it reaches 80% of adult brain volume. In addition, the cerebral cortex is still smooth, and the gyri and sulci are not fully formed, and myelination and inter-neuronal connectivity are still incomplete. Multiple insults during this critical phase of neuronal and glial maturation cause white and gray matter injury, especially in the thalamic region and the periventricular white matter (Kinney, 2006). These events can be correlated subsequently to delayed development and special education needs; therefore it is important to start early developmental follow-up, anticipatory guidance, and interventions for infants born at 32 to 36 weeks' gestation (Chyi et al., 2008).

Hospitalization of the Late Preterm Infant

On the basis of the need for close monitoring and management of the various medical problems identified in late preterm infants, they are more likely than a full-term infant to require admission to an NICU. Despite this, individual hospitals and nurseries follow

• **Fig. 32.9** The immaturity of the laminar position and dendritic arborization of neurons, as demonstrated by Golgi drawings, in the cerebral cortex in the late preterm infant at 35 weeks' gestation is striking in comparison with neurons at midgestation (20 weeks) and at term (40 weeks). (From Kinney HC, Armstrong DD. Perinatal neuropathology. In: Graham DI, Lantos PE, eds. *Greenfield's Neuropathology*. 7th ed, London, United Kingdom: Arnold; 2002:557–559.)

different criteria regarding which infants to admit to the NICU, an intermediate care unit, or an observation area. Some routinely admit all infants born at less than 35 weeks' gestation to the NICU, whereas others do so on an individual basis. The most common reasons for admission include temperature instability, jaundice, respiratory distress, dehydration, poor feeding, and hypoglycemia (Wang et al., 2004; Vachharajani and Dawson, 2009). Studies have shown that 88% of infants born at 34 weeks' gestation, 12% born at 37 weeks' gestation, and 2.6% born at 38 to 40 weeks' gestation were admitted to the NICU (Engle and Kominiarek, 2008). Other studies have shown similar rates, and the overall trend was that the late preterm infant had significantly higher rates of NICU admission than 39-week infants (McIntire and Leveno, 2008; Ananth et al., 2013). In addition, the duration of hospitalization for the late preterm infant is inversely proportional to the baby's gestational age, which means that late preterm infants require longer hospitalization after birth than their full-term counterparts. On average, infants born at 34 weeks' gestation are hospitalized for 6 to 11 days, those born at 35 weeks' gestation are hospitalized for 4 to 6 days, and those born at 36 weeks' gestation are hospitalized for 3 to 4 days (Gilbert et al., 2003; Escobar et al., 2005; Phibbs and Schmitt, 2006; McIntire and Leveno, 2008; Khashu et al., 2009; Vachharajani and Dawson, 2009).

Mortality

Preterm birth is consistently recognized as the most pressing public health problem in perinatology by both clinicians and researchers, given its overall contribution to infant mortality. It also contributes substantially to neurocognitive, pulmonary, and ophthalmologic morbidity (Kramer et al., 2000). In a review of infant birth and death files from 1995 to 2002 in the United States, Tomashek et al. (2007) compared the overall and cause-specific mortality rates between singleton late preterm infants and full-term infants. They found that, despite significant declines since 1995 in mortality rates for late preterm and full-term infants, the infant mortality rate in 2002 was threefold higher in late preterm infants than in

TABLE 32.3 Mortality (Rate Per 1000 Live Births) in Infants Born at Late Preterm and Early Term Gestation

| Gestational Age (Weeks) | EARLY NEONATAL MORTALITY (1–7 DAYS) | | INFANT MORTALITY (1–365 DAYS) | |
|-------------------------|-------------------------------------|------------|-------------------------------|------------|
| | Mortality Rate | Risk Ratio | Mortality Rate | Risk Ratio |
| 34 | 7.2 | 25.5 | 12.5 | 10.5 |
| 35 | 4.5 | 16.1 | 8.7 | 7.2 |
| 36 | 2.8 | 9.8 | 6.3 | 5.3 |
| 37 | 0.8 | 2.7 | 3.4 | 2.8 |
| 38 | 0.5 | 1.7 | 2.4 | 2.0 |
| 39 | 0.2 | 0.8 | 1.2 | 1.2 |

From Young PC, Glasgow TS, Li X, Guest-Warnick G, Stoddard G. Mortality of late-preterm (near-term) newborns in Utah. *Pediatrics*. 2007;119:e659–e665.

full-term infants (7.9 deaths vs 2.4 deaths per 1000 live births); early, late, and postneonatal mortality rates were sixfold, threefold, and twofold higher respectively. Young et al. (2007) found that in a large cohort from Utah, the relative risk of death increased for every decreasing week of gestational age less than 40 weeks (Table 32.3). In addition, a large study involving 133,022 infants born at 34 to 40 weeks' gestation found that neonatal mortality rates were significantly higher for late preterm infants (1.1, 1.5, and 0.5 per 1000 live births at 34, 35, and 36 weeks' gestation respectively compared with 0.2 per 1000 live births at 39 weeks' gestation, $P < .001$; McIntire and Leveno, 2008). In 2005, the US infant mortality rate for late preterm infants was 7.3 per 1000 live births versus 2.43 per 1000 live births in full-term neonates. Surprisingly, the mortality rate is 30% higher even for infants born between 37 and 39 weeks' gestation (early term) (Mathews and MacDorman, 2008). These studies and statistics again emphasize the fact that infants born just a few weeks early are at much greater risk of morbidity and death than those born at term gestation (Ananth et al., 2013; Brown et al., 2014). However, perinatal data collected over similar periods also reveal a remarkable decline in stillbirth rate (Fig. 32.10). Perinatologists argue that this reduction in fetal demise is directly related to close monitoring of the fetus and early intervention (delivery) when needed.

Recommendations

Admission Criteria

With more than 80% of all deliveries in the United States occurring in community hospitals (Jain and Raju, 2013), many of which have a relatively small number of deliveries and healthcare teams that might not always be equipped to assess and manage the needs of a late preterm infant, it becomes increasingly important to establish safeguards for the screening, identification, and appropriate triage of these patients. A subcommittee of the American Academy of Pediatrics Committee on the Fetus and Newborn (Engle et al., 2007) outlined recommendations for the care of the late preterm newborn. On the basis of these guidelines and the potential complications associated with late preterm infants, we recommend

• **Fig. 32.10** Trends in late preterm birth, stillbirth, and infant mortality in the United States, 1990 to 2004. The left axis shows trends in stillbirth and infant mortality rates; the right axis shows trends in late preterm births (34 to 36 weeks). Late preterm birth rates are shown per 100 live births, stillbirth rates are shown per 1000 total births, and infant death rates are shown per 1000 live births. (Modified from Ananth CV, Gyamfi C, Jain L. Characterizing risk profiles of infants who are delivered at late preterm gestations: does it matter? *Am J Obstet Gynecol*. 2008;199:329–331.)

that all infants born before 35 weeks' gestation and/or weighing less than 2300 g should be admitted to a transitional nursery where the infant can be monitored closely until there has been adequate time to assess the baby's vital signs, feeding abilities, and thermoregulation, among other issues, before the baby is sent to the mother's room. Sicker neonates who require intensive care obviously will need to receive higher levels of care. In addition, each nursery should establish guidelines for the frequency of monitoring vital signs, assessment for sepsis and use of antibiotics, and the use of supplemental oxygen. It is also important to determine a threshold (based on comfort level, staff training, and available resources) for transferring the newborn to a tertiary care center when the disease process associated with the late preterm infant continues to progress or worsen. Box 32.3 shows the recommendations for admission, management, and discharge of the late preterm infant. This list is not all-inclusive and was designed to be used as a guideline and not as a replacement for good clinical judgment.

Discharge Criteria

Because of the morbidities and risk factors associated with late preterm babies, they should not be discharged before 48 hours after birth. Before discharge, while the baby is still in the hospital, the following are recommended:

1. Vital signs should be within the normal range for at least 12 hours preceding discharge; this includes respiratory rate less than 60 breaths per minute, heart rate of 100 to 160 beats per minute, and axillary temperature of 36.5°C to 37.5°C in an open crib with appropriate clothing.
2. There should be documentation of passage of at least one stool spontaneously.
3. Adequate urine output should be accompanied by education of the parents about ways to assess the adequacy of output and

• BOX 32.3 Admission and Discharge Criteria and Management of Late Preterm Infants

Admission Criteria

- Admit all infants born before 35 weeks' gestation or weighing less than 2300 g at birth
- They should not be sent to their mother's rooms in the first 24 h until stable, unless arrangements can be made to provide transitional care and close monitoring in the mother's room

Hospital Management

- Physical examination on admission and discharge
- Determination of accurate gestational age on admission examination
- Vital signs and pulse oximetry check on admission, followed by check of vital signs every 3 to 4 h in the first 24 h, and every shift thereafter
- Caution against use of oxyhoods with high FiO_2 ; consider transfer to neonatal intensive care unit or tertiary care center if FiO_2 exceeds 0.4
- A feeding plan should be developed. Formal evaluation of breastfeeding and documentation in the record by caregivers trained in breastfeeding at least twice daily after birth
- Serum glucose screening per existing protocols for infants at high risk of hypoglycemia

Discharge Criteria

- Discharge should not be considered before 48 h after birth
- Vital signs should be within the normal range for the 12 h preceding discharge
- Respiratory rate less than 60 breaths per minute
- Heart rate of 100–160 beats per minute
- Axillary temperature of 36.5°C – 37.4°C measured in an open crib with appropriate clothing
- Passage of one stool spontaneously
- Adequate urine output
- Twenty-four hours of successful feeding: ability to coordinate sucking, swallowing, and breathing while feeding
- If weight loss is greater than 7% in 48 h, consider further assessment before discharge
- Risk assessment plan for jaundice for infants discharged within 72 h of birth
- No evidence of active bleeding at circumcision site for at least 2 h
- Initial hepatitis B vaccine has been given or an appointment has been scheduled for its administration
- Metabolic and genetic screening tests have been performed in accordance with local or hospital requirements
- The late preterm infant has passed a car seat safety test
- Hearing assessment has been performed and the results have been documented in the medical record; follow-up if necessary has been arranged
- Parents have been trained and demonstrate competency in caring for the infant
- Family, environmental, and social risk factors have been assessed; when risk factors are present, discharge should be delayed until a plan for future care has been generated
- Identification of a physician with a follow-up visit arranged for 24–48 h after discharge with a possibility of additional visits initially until the infant can demonstrate a consistent pattern of weight gain.

appropriate interventions if the urine output appears to decrease, with at least 24 hours of successful feeding with adequate coordination of sucking, swallowing, and breathing during feedings.

4. Weight loss should not exceed 7% of birth weight in the first 48 hours of life.

5. Serum or transcutaneous bilirubin level check—A transcutaneous bilirubin level higher than 12 mg/dL should warrant a serum bilirubin level check, which will then be stratified into a risk category by use of a bilirubin nomogram. Parents should also be educated on what to look for and what to do if their baby appears jaundiced.
6. Hearing screen, a car seat test, and metabolic and genetic screening tests should have been performed in accordance with state, local, and hospital protocols; if the baby is circumcised, there should be no bleeding at the site for at least 2 hours.
7. Hepatitis B vaccine should be given or an appointment should be made for its administration.
8. Parents should be educated about umbilical cord and skin care, identification of common signs and symptoms of illness, sleeping patterns and positions, use of the thermometer and the parameters for normal measurements, and responses to an emergency (i.e., CPR training before discharge).

If these guidelines (or other criteria outlined as standard of care) are not met, we recommend considering postponing discharge until the baby has been observed for a longer period and the issues have been resolved.

When additional risk factors are present (e.g., twin or multiple gestation, teenage mother), discharge should be delayed until an appropriate care plan has been generated. In addition, when indicated, it may be appropriate to arrange a nursing home health visit for closer monitoring, but this should not be used to replace the due diligence that must be done while the baby is in the hospital and the appropriate and timely follow-up with a pediatrician.

Follow-Up After Discharge

After discharge from the hospital, most of the medical care a newborn baby receives occurs in two main settings: the primary care physician's office and the emergency department. To avoid fragmented care by multiple emergency department visits and to allow an early assessment of the baby, it is recommended that the late preterm baby be brought for a checkup by its pediatrician within 24 to 48 hours after discharge from the hospital.

In addition, because of their increased risk of developmental delays, these infants should be monitored closely to ensure that all milestones are achieved appropriately and that early intervention (e.g., physical therapy, occupational therapy, speech therapy) is in place if needed. Early developmental testing can also be useful in determining any cognitive delays, which can then be addressed with individualized educational programs.

Readmission to the Hospital

The late preterm infant is susceptible to many of the problems of smaller preterm infants. Because of the multiple factors discussed throughout this chapter, the close observation and intensity of management provided to smaller premature infants are often lacking. In addition, there are often more lenient criteria for discharge, which sets them (and their parents) up for failure and eventual readmission to the hospital. [Tomashek et al. \(2007\)](#) looked at late preterm infants who were discharged early (<2 days after birth) from the hospital and found that 4.3% of late preterm infants and 2.7% of full-term infants were either readmitted or had an observational hospital stay.

Recent data suggest that the most frequent causes of emergency department visits by this subgroup of premature infants after being

discharged home are dehydration, feeding problems, respiratory distress, apnea, fever, infection, and jaundice (Jain and Cheng, 2006). Whether they are evaluated in the emergency department or in a pediatrician's office, it is important to have a lower threshold for readmitting these infants because of their vulnerability to serious complications. Their fragility is evidenced by their higher rate (4.4%) of rehospitalization than for full-term infants (2%; Escobar et al., 2005). In addition, 34- to 36-week infants who were never admitted to the NICU (or if admitted, their NICU stay lasted less than 24 hours) had nearly a threefold and 1.3-fold higher risk of readmission compared with full-term infants respectively (Escobar et al., 2005, 2006). Because late preterm infants are at a much higher risk of rehospitalization, they need close follow-up after discharge to assess breastfeeding and nutrition and to monitor them for jaundice.

Primary care physicians following up late preterm infants in an outpatient setting should also be cognizant that the higher risk of morbidities may persist beyond the neonatal period and into early childhood. One recent study showed that 30% of children younger than 2 years who were admitted to the pediatric intensive care unit for respiratory diseases were born prematurely. Of that group, 17% were former early preterm babies, and 12% were late preterm infants (Gunville et al., 2010).

Outcomes

As previously mentioned, late preterm babies are at a higher risk of long-term morbidities compared with their full-term counterparts. Although the highest risk of psychomotor, behavioral, cognitive, and other developmental disabilities still remains for the extremely low birth weight preterm infants, late preterm infants can also be affected. Late preterm infants often have a more subtle delay in their language skills and academic achievement. In addition, they have higher rates of attention-deficit and behavioral problems than their full-term counterparts (Mahoney and Jain, 2013). Since the distinction between full-term and late preterm infants has only recently been identified, the long-term data on outcomes are still being evaluated. A study on the role of prematurity and maternal factors in first-grade academic failure showed an increased chance of failure on the first-grade Criterion-Referenced Competency Test for former late preterm infants versus former full-term infants (Williams et al., 2013). In addition, two studies by Baron et al. (2009, 2010) looked at outcomes of late preterm infants and full-term infants at the age of 3 years. They found that the late preterm group had significantly lower scores on Differential Ability Scales-II visual spatial, visuomotor, executive function noun fluency, and verb fluency. In their follow-up study, they subdivided the group of late preterm infants into low-risk infants (not admitted to an NICU) and high-risk infants (admitted to an NICU) and found that the difference compared to the full-term group was mainly found in the high-risk group. Therefore they concluded that the increased risk of developmental delay of the high-risk late preterm infants (admitted to an NICU) is secondary to clinical instability, increased morbidities, sex differences, and lower birth weight—with male sex and neonatal morbidities contributing to early cognitive weaknesses. These studies add to the increasing evidence showing the vulnerability of late preterm infants, especially those who required NICU care, and the need for close neurodevelopmental follow-up (Vohr, 2013).

From a respiratory perspective, late preterm infants (even those without any significant respiratory disease in the neonatal period)

have compromised long-term lung function compared with their full-term counterparts. One study (Hoo et al., 2002) of airway function in healthy premature infants with a mean gestational age of 33.2 weeks (who did not have respiratory illness in the neonatal period) showed significantly diminished maximal expiratory flow at functional residual capacity at 1 year of age. Another study (Todisco et al., 1993) evaluated children who were former late preterm infants (without RDS or need for mechanical ventilation during their neonatal period) and compared them with their full-term siblings. They found that the former late preterm children had significantly increased mean residual volumes compared with their siblings. Some studies have also shown an increased risk of asthma in the late preterm population. A retrospective study by Goyal et al. (2011) revealed that compared with full-term babies, late preterm infants had an increased incidence (on the basis of diagnosis) of persistent asthma and increased use of inhaled corticosteroids.

Future Research

Since 1981 the number of premature births in the United States has increased by 30%. Most of this increase is attributable to the increased number of late preterm infants (Pulver et al., 2009)—a unique and high-risk subgroup of premature infants. The identification and care of this group and their unique challenges have only recently been recognized as a high-priority area of research in the field of neonatology. The awareness of the significance of morbidity and disease burden of the late preterm infant has sparked multiple initiatives in the practice of neonatology to address the need for early recognition and specialized care for this patient population. Many birthing hospitals now have late preterm protocols in their postpartum nurseries and NICUs addressing the inpatient care and discharge criteria for these babies as well as closer outpatient follow-up with primary care physicians in their postdischarge care. In addition, changes instituted in the care and timing of delivery of the late preterm gestation mother have also had a significant impact. One multicenter study showed that over a 1-year period, elective scheduled early term deliveries decreased from 27.8% in the first month of the study to 4.8% by the 12th month of the study. In addition, that study also showed that the rates of elective, scheduled, singleton, early term inductions, and cesarean deliveries decreased significantly in the same period (Oshiro et al., 2013). Another advance in the field of late preterm research is that modes of therapy considered standard of care for full-term babies are now being evaluated for their safety and efficacy in the late preterm population. There are several ongoing trials, including one by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, to evaluate the use of therapeutic hypothermia in late preterm babies with hypoxic-ischemic encephalopathy.

There are many questions still to be answered regarding the care and outcomes associated with late preterm infants (Box 32.4). Topping this list of priorities is the need to know which babies are better off being delivered early and, for the rest, what can be done to take pregnancy as close to term as possible. Because answers to many issues related to preterm birth still remain elusive, clinicians have, rightly so, focused on ways to improve the postnatal management of these premature babies. New studies, albeit mostly retrospective, have added to the understanding of the spectrum of morbidities in late preterm infants; they have also formed the basis for current strategies to standardize management and optimize outcomes.

• BOX 32.4 Unanswered Questions and Future Directions

Epidemiology, Trends, Etiology, and Prevention of Late Preterm Births

- Is there a subset of preventable late preterm births?
- What is the effect of continuing such pregnancies (preterm rupture of membranes, preterm labor, medically indicated birth) on perinatal outcomes?
- Is there a role for antenatal administration of steroids in late preterm gestation pregnancies threatened with preterm delivery?
- Should singleton and multiple gestation late preterm deliveries be treated differently?

Clinical Management and Outcomes of Late Preterm Infants

- Can standardized “care paths” for late preterm infants improve outcomes?
- Optimal discharge strategies that minimize readmissions and other problems after discharge
- Strategies for management of rapidly progressive and/or severe morbidities in late preterm infants
- Standardized approach to central nervous system imaging and postdischarge follow-up

Long-Term Outcomes

- Prospective studies of long-term outcomes of symptomatic and asymptomatic late preterm births to determine which infants should have long-term follow-up

Neonatal Pharmacology

KAREL ALLEGAERT, ROBERT M. WARD, AND JOHN N. VAN DEN ANKER

KEY POINTS

- The key feature of neonatal physiology is fast maturation, resulting in extensive variability in pharmacokinetics (PK) and pharmacodynamics (PD), further aggravated by other covariates, including pharmacogenetics (PGx). Variability is the essence of both neonatal care and neonatal pharmacology.
- Thorough understanding of the factors, especially developmental changes, that affect pharmacokinetics (absorption, distribution, metabolism, elimination) in neonates helps to provide accurate dose adjustments to provide effective drug therapy.
- Adverse drug events are frequent and important aspects of drug therapy in neonatal care. Pharmacovigilance is based on prevention, detection, and assessment, but all these issues need to be adapted to the specific characteristics of this population. Minimization or prevention of these kinds of events can be achieved.

Dynamic changes related to growth and maturation in newborns create unique complexities in drug therapy that affect the variability in pharmacokinetics (PK) (absorption, distribution, metabolism, elimination) and pharmacodynamics (PD) (both desired efficacy and unwanted side effects). Pharmacologic studies during this period of rapid growth and physiologic maturation reveal diverse patterns of changes. These patterns also reflect the maturation of different drug-metabolizing enzymes or pathways of elimination throughout infancy. Therapeutic drug monitoring is applied to only a limited numbers of drugs (e.g., phenobarbital, gentamicin), because the concentrations need to correlate with both effects and possible side effects. Dose adjustments to reach the desired concentrations can be estimated at the bedside with use of simple calculations. Pharmacogenetics (PGx) or pharmacogenomics of drug-metabolizing enzymes, transporters, or receptors explains a large part of the observed variations among individuals in their responses to drugs. The immature, preterm, or critically ill newborn adds another level of complexity to this variability in drug disposition and effects.

Principles of Neonatal Therapeutics

In neonates a thorough understanding of factors (“covariates”) that influence drug concentrations will enhance accurate and effective drug therapy and may help identify the causes of treatment failure or therapy-related toxicity. Many relevant covariates are not

incorporated in a therapeutic plan, although the impact on the effectiveness and safety of the investigational drug as well as that of current drug therapy may be tremendous. Since PK (concentration–time profiles) and PD (concentration–effect profiles) in newborns follow the same general principles that govern drug actions in patients of all ages, the diagnosis, drug selection, and administration to achieve a therapeutic goal must consider the impact of *absorption*, *distribution*, *metabolism* and *excretion* on the dose–exposure relationship. In newborns these principles should include special consideration of the unique physiologic and pharmacologic features of these developmentally immature patients (Box 33.1).

Diagnosis

Effective treatment begins with an accurate diagnosis and assessment of symptoms. Although this applies to all areas of therapeutics, treatment in newborns presents specific challenges. Their small size and fragility may preclude useful, but inordinately invasive, diagnostic procedures. For example, newborns with chronic lung disease are treated for “bronchospasm” on the basis of the findings of decreased air entry, desaturation, and abnormal breath sounds. Relief of these symptoms with aerosolized bronchodilators may be interpreted as confirming this diagnosis. Although this may be correct, increased humidity or movement of the endotracheal tube bevel away from a pliable tracheal wall during aerosol treatment may also result in improvement. A similar argument can be made for suspected neonatal infection, the clinical diagnosis of a patent ductus arteriosus, or neonatal pain management. Therefore evaluation of an ineffective therapy should include reconsideration of the diagnosis, in the same way as conclusions about why a therapy succeeded should be made cautiously.

Absorption

Absorption is the movement of a drug into the systemic circulation. It generally requires the crossing of membranes or membrane barriers and is characterized by rate (time to peak) and extent (percentage of dose). The most commonly used route in neonates is *intravenous administration*. However, even this route of administration has challenges related to neonatal pathophysiology and limitations of intravenous infusion systems (e.g., slow flow, small volume, dead space volume, limited flush volume) (Sherwin et al., 2014; Linakis et al., 2016). Consequently, drugs should be infused into the patient as close as possible to the site of the venous

• BOX 33.1 Pharmacologic Principles and Pitfalls in the Management of Very Low Birth Weight Infants

1. Diagnosis:
 - a. Limited diagnostic procedures
2. Absorption:
 - a. Intravenous:
 - I. Drug injection away from patient
 - II. Uneven mixing of drugs and intravenous fluids
 - III. Delayed administration due to very low flow
 - IV. Part of the dose discarded with tubing changes
 - b. Intramuscular:
 - I. Poor perfusion limits absorption
 - II. Danger of sclerosis or abscess formation
 - III. Depot effect
 - c. Oral:
 - I. Poorly studied
 - II. Affected by delayed gastric emptying
 - III. Potentially affected by reflux
 - IV. Passive venous congestion may occur with chronic lung disease, decreasing absorption
3. Distribution (affected by):
 - a. Higher (85%) total body water (versus 65% in adults)
 - b. Lower body fat, i.e., about 1% body weight (versus 15% in term newborns)
 - c. Low protein concentration
 - d. Decreased protein affinity for drugs
4. Metabolism:
 - a. Half-life prolonged and unpredictable
 - b. Total body clearance decreased
 - c. Affected by nutrition, illness, and drug interaction
 - d. Affected by maturational changes
5. Excretion:
 - a. Decreased renal function, both glomerular filtration rate and tubular secretion/absorption

access. If a drug is injected further away from the infant and at a slow rate, the drug may reach the patient far too slowly to achieve effective concentrations. Infusion solution filters may further hamper drug delivery by blocking large molecules, by adsorption of the drug to the filter, or by allowing a heavier drug to settle in the filtration chamber and mix slowly (Sherwin et al., 2014; Linakis et al., 2016). For drugs in which the peak concentration matters (e.g., aminoglycosides) or when the driving force for tissue penetration is a concentration gradient between the circulation and the tissue (e.g., meningitis), these limitations may result in suboptimal therapy.

Intramuscular administration of drugs is used for slow release (e.g., vitamin K, palivizumab) but is a poor substitute for intravenous access and should be avoided for multiple doses. Absorption following intramuscular injection relates to muscle blood flow and depends on maturation and disease characteristics (e.g., hypothermia, shock). Furthermore, intramuscular administration may result in sclerosis of tissues, causing sterile abscesses, or create large intramuscular collections, which are subsequently absorbed slowly, producing a “depot effect” in which serum concentrations rise slowly over time.

Oral administration of drugs is preferred for treatment of chronic illnesses in newborns, but this route is not very well studied in acutely ill preterm neonates. Oral absorption depends on gastric emptying, gastric pH, intestinal motility, intestinal first-pass

metabolism, intestinal surface, and intestinal permeability. All these covariates display maturation and may be affected by disease characteristics (Mooij et al., 2012). Many newborns experience gastroesophageal reflux and delayed gastric emptying. This prolongs and delays absorption, which reduces the peak concentration and may also affect the total dose absorbed. Passive intestinal venous congestion caused by elevated right atrial pressure decreases drug absorption and may do so in premature infants with severe bronchopulmonary dysplasia (Peterson et al., 1980). Coadministration of medications to newborns with small volumes of milk or during continuous gastric or duodenal feedings may also alter absorption.

Buccal, lingual, or rectal administrations are additional enteral routes that are all associated with variability. For clinicians, this means that if enteral drug therapy fails, the impact of the route or feeding patterns on drug absorption must be considered. Finally, unanticipated absorption of drugs intended for topical effects (e.g., cutaneous, inhalation) should be considered but are also associated with relevant side effects (Kearns et al., 2003; Choonara, 2013).

Distribution

Distribution is the partitioning of drugs among various body fluids, organs, and tissues. The distribution of a drug within the body is determined by several factors, including organ blood flow, pH and composition of body fluids and tissues, physical and chemical properties of the drug (e.g., lipid solubility, molecular weight, and ionization constant), and drug transporter activity but also by the extent of drug binding to plasma proteins and other macromolecules (Kearns et al., 2003; Brouwer et al., 2015).

Physiologic differences between preterm neonates, children, and adults affect drug distribution. Total body water content ranges from 85% in premature newborns to 75% in term newborns to 65% in adults (Kearns et al., 2003; Allegaert and van den Anker, 2015a). Conversely, body fat content ranges from 0.7% or less in extremely premature newborns to 12% in term newborns. These differences affect the distribution of water-soluble (e.g., aminoglycosides, acetaminophen), lipophilic (e.g., propofol) drugs or nonpolar drugs (e.g., fentanyl). The protein-binding capacity of drugs in the circulation is lower in early infancy because of lower circulating protein concentrations (e.g., albumin, α_1 -acid glycoprotein) and lower binding affinity. Competitive binding with bilirubin is another specific issue to be considered in neonates (Kearns et al., 2003). With rare exceptions, only the free (unbound) drug crosses membranes, exerts pharmacologic actions, and undergoes metabolism and excretion. However, measurements of drug concentrations usually reflect total circulating drug concentrations, which consist of both free and protein-bound drug concentrations. Thus even when total circulating drug concentrations in the newborn may be low by adult standards, the free drug concentrations may still be equivalent or even higher than those in the adult because of the decreased protein binding.

Metabolism

Drug-metabolizing enzymes are crucial in the extent of drug biotransformation. Although the liver is considered the major organ responsible for drug biotransformation, other organs such as the intestines, lungs, and kidneys also contribute to drug metabolism. These metabolizing enzymes can be classified as participating in nonsynthetic phase I reactions (e.g., oxidation, reduction, hydrolysis) or synthetic phase II reactions (e.g., glucuronidation, sulfation,

acetylation). Their metabolites can subsequently be eliminated by renal, biliary, or other excretion routes and may also be therapeutically active or contribute to adverse effects.

The primary type of enzymes involved in phase I reactions are cytochromes P450 (CYPs). CYPs are microsomal, mixed-function oxidases that catalyze chemical changes within a molecule, such as hydroxylation, methylation, demethylation, addition of oxygen, and removal of hydrogen. There are thousands of different CYPs in plants and animals, on land and in water. CYPs with more than 36% of the same amino acid sequence are grouped as a numbered family (e.g., CYP3). Those with more than 77% polypeptide homology belong to the same subfamily (e.g., CYP3A), and specific genes are denoted with a number (e.g., CYP3A5). The amino acid sequence of these enzymes determines the tertiary structure that creates a hydrophobic pocket with selective binding for chemicals and drugs. This substrate specificity creates groups of drugs, often with similar structure and function, that are metabolized by the same CYP. CYPs mature at different rates and in different patterns. In addition, single nucleotide polymorphisms (SNPs) or substitutions in the DNA sequence for a CYP may reduce its metabolizing activity or completely eliminate it if the polypeptide cannot be formed (cf. PGx). Conversely, some individuals inherit multiple copies of a CYP, producing “supermetabolizers” (CYP2D6). The phase II conjugation enzymes, such as the uridine 5′-diphosphoglucuronosyltransferases (UGTs) have several forms with different substrate specificity (e.g., UGT1A1 for bilirubin, UGT2B7 for morphine) although they are not as absolutely selective as the CYPs.

All enzymes display isoenzyme specific maturation, and this affects drug metabolism throughout infancy. Consequently, the clearance of almost all drugs is decreased in neonates compared with older children and adults, but important variations occur among drug classes and among individuals, which prevents simple generalization. Maturation correlates best with postmenstrual age for some CYPs and with postnatal age for others. Some CYPs do not reach adult activity until the person is several years of age, while others develop activities twice those of the adult during childhood, which shows why generalizations about patterns of CYP maturation are seldom possible. Individual hepatic drug-metabolizing enzymes can be categorized into one of three classes on the basis of their developmental trajectories (*class I*, highest activity in fetal life; *class II*, low phenotypic activity in infancy, increasing at puberty; *class III*, substantial increase in the first months to years of life) (Hines, 2008). Although this classification is very helpful to explain and even predict maturational drug disposition, it should be used cautiously. We cannot simply miniaturize “major” and “minor” routes of elimination as initially documented in adults to (pre)term neonates. In the absence of an adult major route, a minor route, either metabolic or primary elimination, may be a more relevant route of clearance in neonates (e.g., caffeine elimination is through renal elimination in neonates and through metabolic elimination by CYP1A2 in adults). A similar argument can be made for acetaminophen. Glucuronide conjugation is usually low at birth. In contrast, conjugation through sulfation is usually active at birth. These different patterns are reflected in the developmental changes in acetaminophen metabolism in early life (Krekels et al., 2015).

Besides age-driven maturation, other factors such as nutrition, illness, PGx, or drug–drug interactions further affect the phenotypic activity of enzymes and organs responsible for drug metabolism in the newborn. Maturation changes in hepatic blood flow, drug transport into hepatocytes, synthesis of serum proteins, protein

binding of drugs, and biliary secretion further confound accurate predictions about drug metabolism after birth.

Excretion

Drug elimination from the body can occur through several mechanisms, including renal excretion, biliary excretion, transcutaneous loss, and pulmonary exhalation. Renal excretion is the most important pathway for elimination of unchanged drugs or metabolites, either by glomerular filtration or by renal tubular transport activity (reabsorption, secretion).

Glomerular function rises steadily after birth, whereas tubular function matures more slowly, causing a glomerular-to-tubular imbalance (Ligi et al., 2013). Neonatal renal function is diminished both in absolute terms and when normalized to body weight or surface area. The neonatal glomerular filtration rate averages about 30% of the adult rate per unit surface area. The creatinine clearance depends on both gestational and postnatal age and doubles by the end of the first month of life (Vieux et al., 2010). This postnatal increase in glomerular function relates to higher cardiac output, reduced renal vascular resistance, redistribution of intrarenal blood flow, and changes in intrinsic glomerular basement membrane permeability. These age-dependent dynamics of neonatal renal function markedly influence drug excretion. Similar to drug metabolism, however, the variability in renal elimination capacity and drug clearance is further affected by other covariates, such as hypoxemia, nephrotoxic drugs, underperfusion, hypothermia, and intercurrent renal diseases.

Some drugs, such as micafungin, nafcillin, and spironolactone metabolites, are eliminated primarily through biliary excretion. Drugs that are conjugated within the liver may also be excreted through bile only to enter the intestinal tract, where they may be deconjugated and undergo enterohepatic recirculation, similarly to bilirubin. Although biliary excretion is not well studied in newborns, clinical conditions such as parenteral nutrition–associated cholestasis suggest that it may be quite variable among specific patients and conditions.

Transporters play important roles in the uptake or removal of drugs. Compared with enzymes, the ontogeny is still poorly described. A recent review suggests that different developmental patterns for individual transporters are emerging (Brouwer et al., 2015). Organic anion transporter polypeptides provide facilitated transport of anions in many tissues, including the kidney and liver. P-glycoprotein (PGP), the permeability glycoprotein, is an efflux transporter that belongs to the adenosine triphosphate-binding cassette/multiple drug resistance family of transporters and prevents absorption of many compounds across the intestinal wall or into the brain. PGP expression has been described as limited at birth, reaching adult levels at 3–6 months of age (Lam et al., 2015). To put these findings into perspective, the limited PGP efflux activity increases opioid concentrations in the central nervous system of newborns and likely explains the higher incidence of apnea in neonates following opioid exposure.

Pharmacogenetics and Pharmacogenomics

The Human Genome Project has described the structures of many proteins (enzymes, transporters, receptors) that have a role in the PK and PD of many drugs currently used in pediatric and adult pharmacotherapy. Genetic variants that alter activity have been identified, many based on SNPs in these proteins. As mentioned earlier, genetic variation in drug-metabolizing enzymes

can have a significant influence on the relative activity within a particular individual. Large interindividual variation occurs for several isoenzymes and is often explained by inherited differences in activity. Changes in a single nucleotide in the DNA for one of these enzymes is designated with a star, such as CYP2C9*1, and these changes can alter the protein structure enough to decrease, completely inactivate, or increase its enzymatic activity. SNPs have been identified for many CYPs, and ethnic variations in these SNPs help predict when their activity is likely to be reduced or increased. A similar case can be built for drug transporters or receptors.

Knowledge of pharmacogenetic and pharmacogenomic factors that affect PK (metabolism, transport) or PD (receptor) has been important for understanding ways to avoid unanticipated drug effects in adults and to some extent in older children. The aim to individualize pharmacotherapy with the use of PGx reflects the fact that specific effects/side effects are not just randomly distributed but relate to genetic variation in the level of activity of transporters, drug-metabolizing enzymes, and/or receptors. Tailoring neonatal pharmacotherapy to individual patients with use of this knowledge holds great promise for the future and serves as a model of precision medicine in newborns (Allegaert and van den Anker, 2015a; Mooij et al., 2015).

The most commonly applied approach to evaluate PGx in neonates is to search for similar signals initially reported in adults or children (*from adult to newborn* approach). For drug-metabolizing enzymes such as CYP2C19 (pantoprazole dealkylation), CYP2D6 (tramadol O-demethylation), *N*-acetyl transferase 2 (isoniazide acetylation), or UGT2B7 (morphine glucuronidation), the impact of polymorphisms on neonatal drug metabolism has been documented (Allegaert and van den Anker, 2015a). However, these drug-metabolizing enzymes also mature during the first months or years of life. Consequently, it can be difficult to determine to what extent the variability in drug metabolism is explained by genetic expression, maturation, or other covariates. Drug metabolism is often reduced in neonates, and scaling of drug dose by simple body weight or allometrically with an exponential function will not fully compensate for differences in clearance that exist in this newborn population. Clearance often differs severalfold among adults, and the same degree of variation is emerging among neonates, whether due to maturation of the expression of these enzymes by gestational age (GA) or due to induction of protein synthesis after birth.

In addition to this approach, PGx should also be tailored to neonates and only mirror observations initially described in adults. Pharmacogenetic studies may also provide information on the ontogeny of processes that have not yet been well described, such as transporter or receptor ontogeny (pharmacogenetic concordance). A recent illustration of such an exploration is the impact of polymorphisms on neonatal abstinence syndrome following maternal opioid intake. Specific catechol-*O*-methyltransferase (*COMT*, 158 adenine [A] > guanine [G]) and μ -opioid receptor (*OPRM1*, 118A > G) polymorphisms were associated with the extent and the duration of neonatal abstinence syndrome (Wachman et al., 2013). Pharmacogenetic studies may focus on the concordance between genotype and phenotype within cohorts of newborns and young infants. A structured approach to assess the contribution of genetic variation in addition to maturation to pharmacokinetic/pharmacodynamic variability has been suggested and is based on five questions (Leeder, 2009):

1. What gene products (if known) are relevant for the disposition of a given compound?

2. What is the developmental trajectory (if known) of functional (e.g., transporter, enzyme, or receptor) activity?
3. Does allelic variation affect the function(s) of a given compound?
4. Does allelic variation affect the developmental drug disposition phenotype?
5. What is the developmental context of the relevant genes?

Pharmacokinetic Principles

Pharmacokinetics describes the time course of changes in drug concentrations within the body. Although rates of change are often described with differential equations, concepts useful at the bedside are emphasized here. More detailed mathematical discussions of PK can be found elsewhere (Buxton, 2006; Rowland and Tozer, 2010; Anderson, 2012).

Compartment

In PK, *compartment* refers to fluid and tissue spaces into which drugs penetrate. These compartments may or may not be equivalent to anatomic or physiologic volumes. In the simplest case the compartment may correspond to the vascular space and equal the volume of a real body fluid, blood. Large or quite polar molecules may be confined to this central compartment until they are eliminated by excretion or metabolism. Many drugs, however, diffuse reversibly out of the central compartment into tissues or other fluid spaces, referred to generically as *peripheral or tissue compartments*. Diffusion can be driven, in part, by differences in protein binding between compartments or can be affected by active transport (influx/efflux) processes. These kinds of compartments are seldom sampled directly, but their involvement in kinetic processes may be recognized from the graphical or mathematical description of the kinetics of a drug. The number of exponential terms necessary to adequately describe the kinetic profile of a drug designates the number of compartments involved, recognizing that many more compartments may exist. For appropriate clinical application, rarely more than three compartments are required to describe the PK of any drug.

Apparent Volume of Distribution

The apparent volume of distribution might be better termed the *volume of dilution* because it is a mathematical description of the volume (L or L/kg) that dilutes a dose (mg or mg/kg) to produce the observed circulating drug concentration (mg/L or $\mu\text{g/mL}$). To simplify cancellation of units, concentrations are expressed here as milligrams per liter (mg/L), which is the same as micrograms per milliliter ($\mu\text{g/mL}$), the more conventional unit for drug concentrations.

$$\text{Concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Apparent Volume of Distribution (L/kg)}}$$

For many drugs the volume of distribution does not correspond to a specific physiologic body fluid or tissue, hence the term *apparent*. In fact, the volume of distribution for drugs that are bound extensively in tissues may exceed 1.0 L/kg, a physiologic impossibility that emphasizes the arithmetic, nonphysiologic nature of the apparent volume of distribution. The determination of the volume of distribution is described later.

First-Order Kinetics

Removal of most drugs from the body can be described by first-order (exponential or proportional) kinetics, in which a constant *proportion or percentage* of a drug is removed per unit of time (e.g., 50% in one half-life interval), rather than a constant amount per unit of time. Consequently, for drugs exhibiting first-order kinetics, the higher the concentration, the greater the amount removed during a time interval. The following equations describe the concentration (C) of a drug whose first-order kinetics has a rate constant, k (per hour), at time t and an initial concentration of C_0 achieved after administration of a dose.

In differential equation form, the change in concentration with time is:

$$\frac{dC}{dt} = -kC$$

The solution to this differential equation gives the exponential form, which describes C at time t :

$$C_t = C_0 e^{-kt}$$

If this equation is transformed with use of the natural logarithm (\ln), it becomes:

$$\ln C_t = \ln C_0 - kt$$

The last equation is the equation of a straight line, so a graph that plots $\ln C_t$ versus t has an intercept of $\ln C_0$, the concentration at $t = 0$, and a slope of $-k$, the rate constant for the change in concentration. This can be used to calculate the half-life (see the next section) and to estimate appropriate dosages. Multiple rate constants in more complex equations are distinguished with the letter k and numbered subscripts or with Greek letters.

Half-Life

The elimination half-life ($t_{1/2}$) of a drug is the time required for its concentration to decrease by 50%. Consequently, half-life is linked to a first-order kinetic process because the same proportion, 50%, of the drug is removed during equal periods. Half-life can be determined mathematically from the elimination rate constant, k , as:

$$t_{1/2} = \frac{\text{Natural Logarithm } 2}{k} = \frac{0.693}{k}$$

Fig. 33.1 illustrates a graphical method for determination of half-life. Drug concentrations measured serially are graphed on semilogarithmic axes, and the best-fit line is determined either visually or by linear regression analysis. In this illustration of first-order kinetics, the concentration decreases by 50% (from 800–400 mg/L) during the first hour and decreases by another 50% (from 400–200 mg/L) during the second hour. Thus the half-life is 1 hour. More drug is removed during one half-life at higher concentrations, although the proportion removed remains constant. The exponential equation for this graph is:

$$C = 800e^{-0.693t}$$

where $k = 0.693/\text{hour}$ and $C_0 = 800$, allowing a mathematical calculation of half-life with use of the equation previously described:

$$t_{1/2} = \frac{0.693}{k \text{ (/hour)}} = \frac{0.693}{0.693/\text{hour}} = 1 \text{ hour.}$$

• **Fig. 33.1** Apparent single-compartment first-order plasma drug disappearance curve illustrating graphical determination of half-life from the best-fit line of serial plasma concentrations.

• **Fig. 33.2** Multicompartment Serum Drug Disappearance Curve. α , Rate constant for distribution; β , rate constant for terminal elimination.

Multicompartment First-Order Kinetics

The rate of removal of many drugs from the circulation is often biphasic. An initial rapid decrease in concentration is referred to as the distribution (α) phase, often lasting 15–45 minutes, which is followed by a sustained slower rate of removal, the elimination (β) phase. Such biphasic processes are best visualized from semilogarithmic graphs of concentration versus time. When such semilogarithmic graphs show kinetics that best fit two straight lines, the kinetics are described as *biexponential*, or reflective of a drug that shows *two-compartment first-order pharmacokinetics* (Fig. 33.2). Two exponential terms are needed to describe the change in concentration over time, as:

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

In this equation the rate constant for distribution is designated α to discriminate it from the rate constant for terminal elimination (β), where A and B are the $t = 0$ intercepts for the lines describing distribution and elimination respectively. Division by 2.303 converts logarithms to natural logarithms.

After an intravenous dose, drug loss from the vascular space during the distribution phase occurs through both distribution

and elimination (see Fig. 33.2). The rate constant of distribution (α) can be determined by a plot of the difference between the total amount of drug lost initially and the amount of drug lost through elimination (Rowland and Tozer, 2010). This produces the line with the steeper slope (equal to $\alpha/2.303$) below the serum concentration graph in Fig. 33.2. The single slope of the distribution phase and of the terminal elimination phase does not imply that distribution or elimination occurs through a single process. The observed rates usually represent the sum of several simultaneous processes, each with differing rates, occurring in various tissues.

When the time course of drug elimination is observed for prolonged periods, a third rate of elimination, or γ phase, may also be observed and is usually attributed to the elimination of a drug that has reequilibrated from deep tissue compartments back into the plasma. Such kinetics are designated *three-compartment first-order pharmacokinetics*. The kinetics of a drug are expressed with the smallest number of compartments that accurately describes its concentration changes over time.

Apparent Single-Compartment First-Order Kinetics

When a semilogarithmic graph of concentration versus time reveals a single slope with no distribution phase, the kinetics are characterized as *apparent single-compartment first-order kinetics* (see Fig. 33.1). This kind of kinetics can occur when a drug remains entirely within the vascular space or central compartment or when a drug passes very rapidly back and forth between the blood and peripheral sites until it is metabolized or excreted by first-order kinetics. The adjective *apparent* is used because careful study (e.g., very early sampling) often shows that distribution occurs even though the kinetic curve has only a single slope. Single-compartment kinetics implies that the drug rapidly and completely distributes homogeneously throughout the body, which rarely occurs clinically.

In many pharmacokinetic studies in newborns, blood samples are not obtained early enough to allow calculation of the distribution phase, and the kinetics are described as single-compartment kinetics. If sampling begins after the distribution phase, the concentration-time points may fit a single-compartment first-order model, which determines the elimination rate constant (β).

Zero-Order Kinetics

Some drugs demonstrate *zero-order kinetics*, in which a constant amount of drug, rather than a constant proportion or percentage, is removed per unit of time. This relationship can be expressed as:

$$\frac{dC}{dt} = -k$$

It is important to understand when zero-order kinetics occurs, how to recognize it, and how it affects drug concentrations. Zero-order kinetics is sometimes referred to as *saturation kinetics* because it may occur when excess amounts of drug completely saturate enzymes or transport systems such that they metabolize or transport only a constant amount of drug over time. Zero-order processes produce a curvilinear shape in a semilogarithmic graph of concentrations versus time (Fig. 33.3). When drug concentrations are high from a drug overdose or the pathway for elimination is impaired as in renal dysfunction, the kinetics may become zero order initially and be followed by first-order kinetics at lower concentrations. For drugs exhibiting zero-order kinetics, small increments in dose

• **Fig. 33.3** Saturation, or zero-order (serum concentration-dependent), and first-order (serum concentration-independent) pharmacokinetics.

• BOX 33.2 Drugs That Demonstrate Saturation Kinetics With Therapeutic Doses in Newborns

Caffeine
Chloramphenicol
Diazepam
Furosemide
Indomethacin
Phenytoin
Ethanol and other alcohols (excipient)

may cause disproportionately large increments in serum concentration. Certain drugs or excipients administered to newborns exhibit zero-order kinetics at concentrations observed in the clinical setting and must be recognized for potential accumulation (Box 33.2).

Noncompartmental Analysis

Noncompartmental analysis is based on describing drug exposure measured by the area under the concentration-time curve (AUC) without any assumptions about the pattern of elimination or the number of compartments (Buxton, 2006; Rowland and Tozer, 2010; Anderson, 2012). Central to this analysis is the determination of drug clearance from the dose and the AUC:

$$CL = \text{Dose}/\text{AUC}$$

where CL is clearance.

If the dose is administered intravenously, then noncompartmental analysis allows the direct determination of drug clearance with use of this relationship. Estimation of the elimination half-life is generally done with the slope of the log-transformed concentration measurements made during the end of a pharmacokinetic study. With an estimation of clearance and elimination rate, the apparent distribution volume (V) can also be estimated from:

$$CL = V \times k.$$

Thus noncompartmental PK provides a simple means to assess fundamental pharmacokinetic parameters that may be useful for dosing patients when detailed knowledge of the complete pharmacokinetic profile is not available or not needed (Gillespie, 1991).

Population Pharmacokinetics

Most pharmacokinetic studies in the newborn are limited by the amount of blood that can be safely removed for sampling. To determine the kinetics, population pharmacokinetic approaches are valuable, particularly because they can accommodate differences in dose, sampling time, and numbers (O'Hara et al., 2015). The population approach describes the concentration versus time profile for samples in all patients simultaneously, estimating population parameters that describe the average pharmacokinetic profile of the complete study group and patient-specific parameters that define the individual patients in the study. It can use fewer samples taken from each patient, if the samples are taken at different specified times over the complete time profile of interest for the study analysis. For example, one group of 28–32 weeks' gestation neonates might have samples drawn at 1, 4, and 12 hours, while another group of 28–32 weeks' gestation neonates might have blood sampled at 0.5, 2, and 8 hours. The concentrations from these two groups of similar patients are then analyzed in aggregate so as to provide information during both the distribution phase and the elimination phase, thus describing the kinetics with a limited volume of blood sampled from each patient.

Furthermore, the population approach allows the investigation of patient covariates of interest that might explain differences within the population of patients enrolled in the trial. Typical covariates such as postnatal age, GA at birth, weight, sex, and disease conditions can also be assessed for their contribution to differences seen between participants in a clinical study. These covariates can be very helpful for gaining a better understanding of factors that may alter the PK of infants that might otherwise be considered similar. Because of both conditions (fewer samples, exploration of covariates), the use of population pharmacokinetic studies in clinical studies is also strongly supported by the relevant regulatory agencies as an important opportunity to facilitate drug research in this population (Björkman, 2005; Meibohm et al., 2005).

Target Drug Concentration Strategy

Drug treatment of newborns commonly uses the *target drug concentration strategy* (Table 33.1), in which drug therapy corrects a specific problem by producing an effective concentration of free drug at a specific site of action (Anderson and Holford, 2013). The target site of drug action (e.g., central nervous system, subcutaneous tissue) is usually inaccessible for monitoring of concentrations. A specific concentration or range of circulating concentrations is correlated with the effective concentration at the site of action, which provides a “therapeutic” concentration range. However, we should be aware that such target drug concentrations are commonly extrapolated from other patient populations and are only rarely validated in newborns (Allegaert and van den Anker, 2015a).

The requirements for effective and accurate application of the target drug concentration treatment in adults have been discussed by Spector et al. (1988). When applied to newborns, these requirements highlight the special problems of drug therapy in these

patients and the special circumstances in which clinical drug concentration monitoring is appropriate. Some of these requirements are as follows:

- Availability of a reliable, valid analytic procedure for accurate measurement of drug concentrations in small volumes of blood
- A wide variation in PK among individuals with the knowledge that population-based kinetics do not accurately predict individual kinetics
- Drug effects proportional to plasma drug concentrations
- A narrow concentration range between efficacy and toxicity (narrow therapeutic index)
- Constant pharmacologic effect over time, in which tolerance does not develop
- Clinical studies that have determined the target and toxic drug concentration ranges

Therapeutic Drug Monitoring

Table 33.1 describes the basic assumptions of therapeutic drug monitoring: the total plasma drug concentrations correlate with dose but also with the circulating unbound drug concentrations and the unbound drug concentration at the site of action. Clinical measurements of drug concentrations are usually total drug concentrations, while the active portion is the unbound portion (see the discussion of distribution). Two broad indications for monitoring drug concentrations are to (1) attain effective concentrations and (2) avoid toxic concentrations. However, drug concentration ranges are not absolute reflections but only indirect markers of effective therapy. Patient response, not a specific drug concentration range, is the end point of therapy.

Although the concentrations of aminoglycoside or glycopeptide antibiotics are monitored frequently in newborns, the current perception is that toxicity is much more rare in newborns than in adults (Bhatt-Mehta et al., 1999; Kent et al., 2014). Because of the limited evidence of toxicity in newborns, it is more important to measure these concentrations to achieve effective concentrations for treatment of culture-proven infections than to avoid toxicity. In newborns with serious therapeutic problems, measurement of serum drug concentrations should be used to achieve effective concentrations as well as to avoid toxicity. When the desired concentration range and kinetic parameters are known, doses may be estimated to reach that concentration with single bolus doses or bolus doses followed by continuous infusions.

Pharmacokinetic-Based Dosing

The following equations can be used both to guide dosing and to derive kinetic parameters for individual patients.

$$\text{Dose} = \Delta C \cdot V_d = [C_{\text{desired}} - C_{\text{initial}}] \cdot V_d$$

$$(\text{mg/kg}) = (\text{mg/L}) (\text{L/kg}) = (\text{mg/L}) (\text{L/kg})$$

where C is the concentration and V_d is the volume of distribution.

TABLE 33.1 Target Drug Concentration Strategy

| | | | | | | | | |
|-----------|---|---------------------------------|---|-----------------------------------|---|--|---|------------------------------|
| Drug dose | ↔ | Plasma total drug concentration | ↔ | Plasma unbound drug concentration | ↔ | Target site unbound drug concentration | ↔ | Desired pharmacologic effect |
|-----------|---|---------------------------------|---|-----------------------------------|---|--|---|------------------------------|

This equation may be used to estimate dosage changes needed to increase or decrease concentration. For the first dose, the starting concentration is zero; for doses after the first, the calculation of the volume of distribution should use the change (Δ) in concentration from the preceding trough to the peak associated with that dose. To reach a desired concentration rapidly, a loading dose can be administered, followed by a sustaining infusion. The equation for calculation of infusion doses to maintain a constant concentration is as follows:

$$\begin{aligned}\text{infusion rate} &= k \cdot V_d \cdot C \\ (\text{mg/kg}) (\text{min}^{-1}) &= (\text{min}^{-1}) (\text{L/kg}) (\text{mg/L})\end{aligned}$$

where C is the concentration, V_d is the volume of distribution, and k is the rate constant of elimination.

A steady state is reached when tissue concentrations are in equilibrium and the amount of drug removed equals the amount of drug infused. The time needed to reach a steady state depends on the elimination half-life. While the time needed is *not* shortened by the administration of a loading dose, a loading dose can allow the patient to achieve therapeutic concentrations rapidly, and these can be maintained with an infusion during the steady state.

It is important to consider that if drug clearance decreases, the steady-state concentration during an infusion will increase proportionally. Additionally, the half-life increases and the rate constant decreases. Since concentrations are not measured for most of the drugs administered by continuous infusion in the neonatal intensive care unit (NICU), it is important to adjust dosages for factors that reduce clearance, such as kidney or liver dysfunction or reduced kidney or liver blood flow, to avoid high and toxic concentrations.

Repetitive Dosing and the “Plateau Principle”

During the typical course of drug therapy, drug doses are administered before complete elimination of previous doses, and the drug accumulates in the body (Rowland and Tozer, 2010). As a consequence, during repeated administration, the peak and trough concentrations after each dose will increase until a steady-state situation has been reached. *Steady-state*, or *plateau*, concentrations are reached when the amount of drug eliminated equals the amount of drug administered during each dosing interval. During repetitive dosing, the steady-state concentrations achieved are related to the half-life, dose, and dosing interval relative to the elimination half-life (Rowland and Tozer, 2010; Buxton, 2006).

Fig. 33.4 illustrates a hypothetical concentration–time curve for a drug with a half-life of 4 hours administered orally every 4 hours, so the dosing interval corresponds to one half-life. Several important principles of PK are illustrated in Fig. 33.4, with the mathematics described in detail elsewhere (Buxton, 2006). Drug concentrations rise and fall with drug administration (absorption) and elimination. For dosing intervals of one half-life, accumulation is 88% complete after the third dose, 94% complete after the fourth dose, and 97% complete after the fifth dose. At steady state, the peak and trough concentrations between doses are the same after each dose. If a drug is administered with a dosing interval equal to one half-life, the steady-state peak and trough concentrations are two times those reached after the first dose. If the dosing interval is shortened to half of a half-life, the concentration decreases less before the next dose, more total drug is administered per day, and the steady-state peak and trough concentrations are considerably higher (3.4 times the peak and trough

• **Fig. 33.4** Multiple dosing with accumulation of serum drug levels to the steady-state concentration.

concentrations after the first dose). Therefore the shorter the dosing interval to half-life ratio, the higher the drug accumulation. As noted during infusions, the *length of time* required to reach steady-state concentrations depends primarily on the elimination half-life, not the dosing interval.

Clearance

Clearance of drugs, as for creatinine, describes the *volume of blood* from which all the drug is removed per unit of time. Clearance is proportional to organ blood flow and the intrinsic capacity of organs to metabolize or remove a drug from the circulation. In its simplest form, clearance is proportional to the flow to a single organ (Q) and to the arterial–venous difference in drug concentrations compared with the amount of drug in the circulation, expressed as follows:

$$CL = Q \cdot \frac{C_{\text{arterial}} - C_{\text{venous}}}{C_{\text{arterial}}}$$

Total body clearance usually reflects the combined clearance of multiple organs with different enzyme activities and different rates of blood flow. Clearance can be measured by the rate of appearance of a drug outside the body (such as urinary creatinine clearance) or by the rate of disappearance of a drug from the blood compared with the blood concentration. For calculations, *clearance* is defined as the dose divided by the area under the plasma AUC and by the rate of drug input per steady-state concentration (C_{ss}) average, where the rate of input is the dose/dosing interval (τ). For a drug administered by continuous infusion, this is simply the infusion rate (milligrams per kilogram per hour) divided by C_{ss} as follows:

$$CL = \frac{\text{Dose}}{\text{AUC}} = \frac{\text{Dose}/\tau}{C_{ss}} = \frac{\text{Infusion Rate}}{C_{ss}}$$

Once clearance is known, this equation can be rearranged to solve for the dose necessary to achieve any desired steady-state concentration:

$$\begin{aligned}\text{Infusion Rate} &= C_{ss} \cdot CL \\ (\text{mg/kg})\text{hr}^{-1} &= (\text{mg/L}) (\text{mL/kg})\text{hr}^{-1}\end{aligned}$$

Total body clearance changes significantly for several drugs during the period of fetal and infant development because renal clearance and/or the activity of drug-metabolizing enzymes increase with advancing gestational and/or postnatal age. If available, values for clearance and the volume of distribution at different stages of

development can be used to estimate the dosages needed to achieve and maintain “therapeutic” concentrations associated with desired clinical responses.

To illustrate this for renal clearance, a higher dose (mg/kg) and a further extended time interval are applied for aminoglycosides or vancomycin to compensate for the higher distribution volume (peak concentration) and the lower renal clearance (trough concentration) (Janssen et al., 2015; Valitalo et al., 2015). Studies of the analgesic fentanyl illustrate the developmental changes in metabolic clearance and, as a consequence, its kinetics and how they may be used to calculate dosages to reach and maintain concentrations associated with effective analgesia. Analgesia has been associated with a serum fentanyl concentration of 1–2 ng/mL (Santeiro et al., 1997). If analgesic treatment is initiated with a continuous infusion of fentanyl, five half-lives are needed to reach a steady state. The fentanyl half-life ranges from 3 hours in term newborns to 12.7 hours in preterm newborns (Koehntop et al., 1986; Santeiro et al., 1997). Because of this prolonged half-life, the patient may be inadequately treated for a long time unless a loading dose is administered to reach an effective concentration more rapidly. In general, initiation of analgesic treatment and increases in infusion dosages of analgesics should begin with a loading dose based on the estimated volume of distribution in the central compartment (circulation) and the desired concentration. Use of a loading dose shortens the time to reach higher effective analgesic concentrations but also increases the likelihood of toxicity, as has been reported with digoxin.

Limited data are available regarding the GA-related changes in fentanyl clearance, but two studies show that it increases with advancing GA (Koehntop et al., 1986; Santeiro et al., 1997) and postnatal age (Gauntlett et al., 1988; Santeiro et al., 1997). The linear graph of clearance versus gestational age from 38 neonates in whom treatment began within 47 hours after their birth was used to derive mean rates of clearance at different GAs as shown in Table 33.2.

Other investigators studied single-dose fentanyl kinetics during anesthesia and found an apparent central volume of distribution of fentanyl in neonates of 1.45 L/kg (Koehntop et al., 1986). This distribution volume is smaller than the steady-state volume of distribution of 5.1 L/kg also calculated after a single dose of fentanyl (Koehntop et al., 1986). In turn, the apparent steady-state volume of distribution after a single bolus dose of a lipophilic drug is usually smaller than that associated with continuous drug infusions, during which tissues throughout the body become saturated with drug. The steady-state distribution volume for fentanyl during continuous infusions was calculated as 17 L/kg (Santeiro et al.,

1997). Because fentanyl is a highly lipid-soluble drug, it distributes rapidly from the central compartment into the peripheral tissue compartment. This large distribution volume likely reflects the period during the infusion when drug is leaving the circulation to penetrate peripheral tissues, such as fat. Because it may take 15–60 hours to achieve a steady-state concentration (five half-lives) after a fentanyl infusion is begun or the infusion rate is increased, a patient may need repeated bolus doses to maintain effective plasma concentrations in the central compartment. The best approach is to repeat the calculated loading dose until the desired clinical effect is achieved. This also illustrates why, for sedation specifically, dosing should be adjusted to achieve the desired clinical effect. Clearance calculations, however, can guide the starting dosages to achieve effective sedation, as illustrated later.

The kinetic parameters for fentanyl in premature newborns reported by Koehntop et al. (1986) can be used to calculate a loading and infusion dose to reach a fentanyl concentration of 2 ng/mL, which is considered an analgesic concentration (Saarenmaa et al., 2000). This is estimated for a premature newborn at a GA of 33 weeks (note that nanograms per milliliter is equivalent to micrograms per liter) as:

$$C (\mu\text{g/L}) = \frac{\text{Load Dose } (\mu\text{g/kg})}{V_{d_{\text{central}}} (\text{L/kg})}$$

$$\begin{aligned}\text{Load Dose } (\mu\text{g/kg}) &= 2 (\mu\text{g/L}) \cdot 1.45 (\text{L/kg}) \\ &= 2.9 \mu\text{g/kg}\end{aligned}$$

$$\begin{aligned}\text{Infusion Rate } (\mu\text{g/kg} \cdot \text{h}) &= C (\mu\text{g/L}) \cdot \text{CL} (\text{mL/kg} \cdot \text{h}) \\ &= 2 \mu\text{g/L} \cdot 11.4 \text{ mL/kg/min} \\ &\quad \cdot 1 \text{ L/1000 mL} \cdot 60 \text{ min/h} \\ &= 1.4 \mu\text{g/kg} \cdot \text{h}\end{aligned}$$

Two studies have observed increases in fentanyl clearance with advancing postnatal age (Gauntlett et al., 1988; Santeiro et al., 1997). This postnatal increase in clearance of fentanyl likely relates either to maturation of CYP3A4 (the enzyme responsible for fentanyl metabolism) activity or to increased hepatic blood flow after birth, because fentanyl has a high hepatic extraction rate. For drugs such as fentanyl with a high hepatic extraction rate, the rate-limiting factor in clearance is the flow of blood to the liver (Saarenmaa et al., 2000). Some researchers have observed that increased intra-abdominal pressure reduces fentanyl clearance, which is likely caused by reduced hepatic blood flow (Koehntop et al., 1986; Gauntlett et al., 1988). Clinical changes known to increase or decrease fentanyl clearance should be used to adjust starting dosages, but dosing should be adjusted primarily for the desired clinical effect. Such an approach should also consider subsequent development of drug tolerance (i.e., that a higher concentration is needed to attain a similar effect).

Modeling and Simulations

Pharmacokinetic modeling and simulations can be used to estimate the impact of important developmental changes and disease processes on pharmacokinetic parameters for distribution volume, elimination rate, and total body clearance. These can identify clinical situations and conditions when dosages are likely to require modification (e.g., drug–drug interactions, genetic polymorphisms, renal impairment). Mathematical simulations create theoretical pharmacokinetic profiles for patients after a dose using the range of pharmacokinetic

TABLE 33.2 Developmental Pharmacokinetics of Fentanyl

| Gestational Age (Weeks) | Clearance at 0–47 h After Birth (mL/min kg) |
|-------------------------|---|
| 29 | 9.6 |
| 33 | 11.4 |
| 37 | 13.2 |
| 41 | 15.0 |

Data from Saarenmaa E, Neuvonen PJ, Fellman V. Gestational age and birth weight effects on plasma clearance of fentanyl in newborn infants. *J Pediatr*. 2000;136:767–770.

parameters determined from a patient population. These can then be calculated for 100–1000 hypothetical patients to define the expected range of concentrations that are likely after a dose. For drugs such as anti-infectives with which serum concentrations have been correlated with effectiveness, this provides estimates of how large a dose is needed to reach effective concentrations. A study on fluconazole kinetics in newborns illustrates this application (Wade et al., 2008). Modeling and simulation methods can also be used for clinical study design to support decisions about the number of participants, optimal times of sampling, covariates, phenotypic analyses, and population analyses.

Clinical Applications of Pharmacokinetics

How to Estimate Dose Adjustments

Gentamicin and phenobarbital will be used to illustrate the clinical application of the principles of PK and therapeutic drug monitoring discussed earlier. The calculations can be performed with standard arithmetic calculators and provide close enough estimates of the kinetics for drugs with a long half-life to adjust dosages at the bedside.

Gentamicin

Assume that the optimal gentamicin target concentrations are:

$$\begin{aligned}\text{Peak} &= 6\text{--}10\ \mu\text{g/mL} \\ \text{Trough} &= 0.5\text{--}2\ \mu\text{g/mL}\end{aligned}$$

Following the fourth conventional dose (4 mg/kg) of gentamicin to a hypotonic premature newborn, the peak concentration was 4.5 $\mu\text{g/mL}$; 18 hours after the peak was obtained, the trough was 2.25 $\mu\text{g/mL}$. It appears that the distribution volume is greater than anticipated, because the peak concentration is lower than expected, and the half-life is longer than anticipated, because the trough is higher than expected. The time of drug administration and that of blood sampling was confirmed (an important step), so the half-life is 18 hours, because the concentration decreases by 50% from 4.5–2.25 $\mu\text{g/mL}$ in 18 hours (assuming that the kinetics are exponential and first order).

$$\begin{aligned}\text{Vd (mL/kg)} &= \text{Dose (mg/kg)} \times (1000\ \mu\text{g/mg}) / \Delta C\ (\mu\text{g/mL}) \\ &= 4.0\ (\text{mg/kg}) \times 1000 / 4.5 - 2.25\ (\mu\text{g/mL}) \\ &= 4000\ \text{mL} / 2.25\ \text{kg} = 1.777\ \text{mL/kg}.\end{aligned}$$

To ensure a trough concentration of 2.0 $\mu\text{g/mL}$ or less, doses are administered every two half-lives, or every 36 hours. When two half-lives have passed after the fourth dose, the gentamicin concentration should be about 1.1 $\mu\text{g/mL}$ (50% of 2.25 $\mu\text{g/mL}$). Increasing the concentration from the 1.1 $\mu\text{g/mL}$ trough to more than 6 $\mu\text{g/mL}$ requires a concentration difference of 4.9 $\mu\text{g/mL}$ or more. With a distribution volume of 1.777 mL/kg, a dose of 8.7 mg/kg should raise the concentration from a trough of 1.1 $\mu\text{g/mL}$ to a peak of 6.00 $\mu\text{g/mL}$.

$$\begin{aligned}\text{Vd (mL/kg)} &= \text{Dose (mg/kg)} \times (1000\ \mu\text{g/mg}) / \Delta C\ (\mu\text{g/mL}) \\ 1.777\ \text{mL/kg} &= \text{Dose (mg/kg)} \times (1000\ \mu\text{g/mg}) / 4.9\ (\mu\text{g/mL})\end{aligned}$$

$$\text{Dose (mg/kg)} = (1.777/1000) / \text{kg} \times 4.9\ \text{mg} = 8.7\ \text{mg/kg}.$$

In one half-life, this concentration will decrease to 3.0 $\mu\text{g/mL}$, and in two half-lives, or 36 hours, it will decrease to 1.5 $\mu\text{g/mL}$.

Another 8.7 mg/kg dose will raise the peak concentration by 4.9 $\mu\text{g/mL}$ to 6.4 $\mu\text{g/mL}$, which will fall to 3.2 $\mu\text{g/mL}$ in one half-life and to 1.6 $\mu\text{g/mL}$ in two half-lives. The variation between the peak and trough concentrations after the last dose is within the desired range for the optimal gentamicin concentrations defined previously.

Phenobarbital

Seizures that were hard to control developed in a 3.6-kg asphyxiated newborn. Seizures continued after two 20 mg/kg phenobarbital doses until an additional 10 mg/kg dose was administered. A maintenance dose of 7 mg/kg per day was started 24 hours after the loading doses were administered. At 10 days, this child was increasingly somnolent. The phenobarbital level measured in a blood specimen drawn 2 hours after administration of the oral maintenance dose was 50 $\mu\text{g/mL}$. Additional doses were withheld, and the phenobarbital concentration was checked daily; the results were as follows:

- 24 hours: 40 $\mu\text{g/mL}$
- 48 hours: 31 $\mu\text{g/mL}$
- 72 hours: 25 $\mu\text{g/mL}$
- 96 hours: 21 $\mu\text{g/mL}$

The maintenance dose (7 mg/kg) was resumed immediately after the 21 $\mu\text{g/mL}$ concentration was measured and produced a peak concentration of 30 $\mu\text{g/mL}$ after administration of the dose. These concentrations and dosages can be used to calculate the volume of distribution and a dose to maintain the phenobarbital concentration between 20 and 30 $\mu\text{g/mL}$ as:

$$\begin{aligned}\text{Vd (L/kg)} &= \frac{\text{Dose (mg/kg)}}{\Delta C\ (\mu\text{g/mL} = \text{mg/L})} \\ &= \frac{7.0\ (\text{mg/kg})}{(30 - 21)\ (\text{mg/L})} \\ &= \frac{7\ (\text{mg/kg})}{9\ (\text{mg/L})} \\ &= 0.78\ \text{L/kg}\end{aligned}$$

Half-life can be estimated from inspection, because the concentration decreased from 50–25 $\mu\text{g/mL}$ in 72 hours. Thus it should take 72 hours for the concentration to decrease by one half-life from 30–15 $\mu\text{g/mL}$. Assuming that the elimination rate does not change, the concentration will decrease approximately 5 $\mu\text{g/mL}$ every 24 hours, or one-third of a half-life. Dividing the half-life into fractions is an approximation because it estimates the change in concentration as linear rather than exponential. To be more accurate, the concentration decreases by 59% in half of one half-life. Although this approximation violates certain principles of PK, it allows estimation of the change in concentration for each one-third of a half-life as one-third of the change during one half-life. Thus the concentration decreases by about 5 $\mu\text{g/mL}$ in 24 hours. The following approach can be used to estimate the daily phenobarbital dose needed to return the concentration to 30 $\mu\text{g/mL}$, a change in concentration of 5 $\mu\text{g/mL}$:

$$\begin{aligned}\Delta C\ (\text{mg/L}) &= \frac{\text{Dose (mg/kg)}}{\text{Vd (L/kg)}} \\ 5\ (\text{mg/L}) &= \frac{\text{Dose (mg/kg)}}{(0.78)\ (\text{L/kg})} \\ 3.6\ \text{mg/kg} &= \text{Dose (mg/kg)}\end{aligned}$$

Drug-Induced Illness

In a prospective study on the epidemiology of adverse drug reactions (ADRs) in 200 consecutively admitted neonates, 136 ADRs occurred in 60 neonates (30%), 20 were life threatening, and 24 were of moderate intensity (prolonged hospital stay) and about 50% of the neonates had multiple ADRs (Aranda et al., 1982). In a more recent study of a mixed population of 313 neonates admitted to the NICU or the intermediate care unit, 116 ADRs occurred in the neonates (17%), and 44% of these ADRs needed specific treatment (Belén Rivas et al., 2015). The reasons behind drug-related morbidity and mortality are diverse and complex. In addition to a lack of specific labeling for this special patient population, absence of age-appropriate neonate-friendly formulations and a high frequency of (poly)pharmacy, there is also the immature organ function and substantial comorbidities that will further increase the risks of ADRs in neonates (Allegaert and van den Anker, 2015b).

Legislative initiatives have resulted in a substantial increase in pharmacologic studies in children, with, as a consequence, a significant increase in label changes. Unfortunately, only a few included drug label changes for neonates (Laughon et al., 2014; Stiers and Ward, 2014). Neonatologists should realize that almost all compounds currently used in neonates were initially developed for other patient populations, with subsequent tailoring to neonates. Recently, the International Neonatal Consortium has been developed as part of the Critical Path Initiative to serve as a forum for the neonatal community to develop consensus statements (e.g., standardization of methods, standard-of-care consensus statements, population-specific biomarkers, modeling approaches, trial designs, clinical outcome assessment tools, formulation issues) with the ultimate goal to improve neonatal medicine development (International Neonatal Consortium, 2016; Davis and Turner, 2015).

Furthermore, drug-induced illness is rarely considered, and failure to recognize drug-induced illness in the newborn often results in continued or intensified pharmacologic interventions rather than discontinuation of treatment. To improve its detection, Du et al. (2013) suggested and validated an algorithm to detect ADR in neonatal intensive care. Prudent care of newborns must recognize and weigh the potential benefits of unstudied drug therapy against potential drug-induced morbidity and mortality. Some examples from the (recent) history of drug-induced mortality and morbidity should serve as a reminder of how more harm than good may accrue from uncontrolled, unstudied pharmacotherapy in neonates.

Illustrations of Drug-Induced Illnesses in Neonates

Chloramphenicol was released in the 1940s, and the recommended dosages were 50–100 mg/kg per day for patients weighing 15 kg or less. Before 1959, the year that Sutherland (1959) reported three cases of sudden death in newborns treated with high dosages of chloramphenicol (up to 230 mg/kg per day), the drug was considered “well tolerated and nontoxic” (Sutherland, 1959). Burns et al. (1959) reported the disturbing results of a controlled trial of the following four prophylactic treatment regimens for newborn sepsis: (1) no treatment, (2) chloramphenicol alone, (3) penicillin and streptomycin, and (4) penicillin, streptomycin, and chloramphenicol. The groups that received chloramphenicol (100–165 mg/kg per day) had higher mortality rates (60% and 68%), and the deaths of these newborns demonstrated the stereotyped sequence of symptoms and signs caused by chloramphenicol accumulation,

coined *grey baby syndrome* (Burns et al., 1959). This syndrome consisted of abdominal distention, poor peripheral perfusion and cyanosis, vasomotor collapse, irregular respirations, and death within hours of onset of these symptoms.

The discovery of the mechanism (glucuronidation deficiency) of chloramphenicol toxicity in newborns illustrates several important aspects of neonatal pharmacology. Because chloramphenicol was considered well tolerated in older children and adults, it was regarded as nontoxic to newborns. Higher doses were administered to newborns despite recognition that its clearance required glucuronide conjugation, which was known to be immature in newborns. The unexpected finding that chloramphenicol in dosages of 100–165 mg/kg per day could be lethal to newborns was demonstrated because the study conducted by Burns et al. (1959) included appropriate control groups. Similar case observations with the mechanism involved are summarized in Table 33.3 to illustrate that the same kind of observations can still be seen.

Reduction and Prevention of Medication Errors in Newborn Care

In two studies performed in NICUs, about one-third of the “iatrogenic” events were preventable, one-quarter related to drugs (Ligi et al., 2008; Kugelman et al., 2008). For drug errors, ordering and prescription as well as administration-related errors were observed. The top five preventable errors relate to incorrect doses, medications that are inappropriate for the medical condition, failure to monitor newborns for drug-related side effects, failure of communication, and failure to monitor drug levels. While many errors are inconsequential, others result in serious adverse effects. Medication errors incur significant costs, ranging from obvious ones such as direct patient injury, prolonged hospital stays, and additional corrective treatments to more subtle ones such as the costs associated with monitoring and regulation of medication use (Ligi et al., 2008; Kugelman et al., 2008).

The process for ordering, preparing, dispensing, and administering medications is often complicated and may contribute directly to errors. The frequency of those errors, however, may be reduced in almost every unit. A barcode medication administration system (verification of drug and patient), in combination with a double check when further manipulation (such as dilution) is needed, is required to effectively reduce this burden of targeted, preventable medication errors in the NICU setting (Morriss et al., 2009). Although these kinds of complex and expensive computerized systems may help reduce medication errors, caregivers can take steps that are completely within their control to reduce medication errors without waiting for changes in the entire pharmacy process within the hospital. Prescriptions and drug orders are a means of communicating, yet clinicians often devote too little attention to make these documents legible, clear, and unambiguous (ASHP guidelines on preventing medication errors in hospitals, 1993). Physicians should keep the following recommendations in mind to ensure that they communicate their medication orders more effectively:

- Write out instructions rather than use abbreviations.
- Avoid vague instructions (e.g., “take as directed”).
- Specify exact dosage strengths.
- Avoid abbreviations of drug names (e.g., MS could mean morphine sulfate or magnesium sulfate).
- Avoid “U” as an abbreviation for units as the “U” may be mistaken for a “0.”
- Avoid trailing zeroes (e.g., 5.0 mg).

TABLE 33.3 Illustrations of Formulation (Active Compound, Excipient)-Specific Drug-Induced Illnesses in Neonates and the Mechanism Involved

| Compound/Formulation | Clinical Syndrome | Mechanism Involved |
|---------------------------------|-------------------------|---|
| Sulfonamides (1956) | Kernicterus | Highly albumin bound antibiotic, competitive with endogenous compounds, including bilirubin. This results in higher free bilirubin level and subsequent kernicterus. |
| Benzyl alcohol (1982) | Gasping syndrome | Benzyl alcohol, coadministered as preservative in parenteral formulations results in accumulation in preterm neonates because of their limited metabolic (alcohol dehydrogenase) clearance capacity. Accumulation results in metabolic acidosis followed by seizures, bradycardia, gasping respirations, hypotension preceding cardiovascular collapse, and ultimately death. |
| Dexamethasone (2000) | Cerebral palsy | High-dose dexamethasone exposure in neonatal life results in an increased risk of displaying cerebral palsy during infancy, likely due to increased neuroapoptosis. |
| Lopinavir/ritonavir (2005) | Alcohol accumulation | Lopinavir/ritonavir (Kaletra) syrup contains both ethanol and propylene glycol. Impaired metabolism results in accumulation and subsequent hyperosmolality, lactic acidosis, renal toxicity, central nervous system impairment, cardiac arrhythmia, hemolysis, and collapse. |
| Ceftriaxone plus calcium (2009) | Cardiovascular collapse | Simultaneous administration of calcium-containing infusions and ceftriaxone results in intravascular precipitation, as observed during autopsy. |

- Use leading zeroes (e.g., 0.5 mg).
- Minimize the use of verbal orders.
- Ensure that prescriptions and signatures are legible, even if it means printing the prescriber's name that corresponds to the signature.

Changes in the pharmacy process can also be effective, as highlighted by [Campino et al. \(2016\)](#) who evaluated the impact of a care bundle intervention (protocol standardization, education) on the number of errors and documented significant reductions in both calculation errors (1.35%–0%) and accuracy error rates (from 54.7%–23% at the bedside and from 38.3%–14.6% in the hospital pharmacy) ([Campino et al., 2016](#)).

Drug Excretion in Breast Milk

The excretion of drugs in breast milk remains a source of confusion and concern for many physicians and families ([National Institutes of Health](#)). However, knowledge is increasing, and access to this knowledge through, for example, LactMed (<http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>) is improved. The Pregnancy and Lactation Labeling Final Rule should also provide a tool to generate and collect more reliable information on maternal drug use during

breastfeeding. A common misconception about safety is “*when in doubt, do not provide breastfeeding*,” since breastfeeding itself provides benefits to the infant and the mother. On average, the nursing infant receives around 2%–3% of a maternal dose through milk, but drugs that are organic bases or are lipid soluble may reach higher concentrations in milk than in maternal serum, but this should not by definition affect the infant. To illustrate this more balanced approach, breastfeeding in infants of women taking antiepileptic drugs was associated with an improved neurodevelopment outcome compared with those who either did not breastfeed or breastfed for less than 6 months ([Meador et al., 2014](#)). Similarly, breastfeeding by opioid-taking women may help to control neonatal abstinence syndrome but may also be associated with neonatal oversedation ([Iseman et al., 2011](#); [Lefevre and Allegaert, 2015](#)). Overall, the available data regarding drug exposure of the newborn through human milk have been organized, in decreasing levels of concern, from drugs that are associated with adverse effects on the infant during nursing to those that are of concern pharmacologically to those that have not been associated with problems during nursing. The list of drugs that clearly cause problems during nursing is surprisingly short ([American Academy of Pediatrics Committee on Drugs, 2001](#)).

Summary

Drug therapy for newborns requires application of the basic principles of PK (drug absorption, distribution, metabolism, and excretion) and PD to estimate and individualize dosages. However, owing to a lack of GA-appropriate kinetic data in the rapidly changing fetus and newborn, drug therapy is still commonly based on empiric, off-label prescriptions. Combined with the extensive drug exposure of neonates in the NICU, this is hazardous and likely explains the high frequency of adverse, sometimes fatal, drug reactions. Methods appropriate for the study of therapeutics in

newborns present unique difficulties, but recent legislative and methodological progress provides additional assistance for investigators and helps advance this area of pharmacology ([Jacqz-Aigrain 2011](#); [US Congress, 2012](#); [Leong et al., 2012](#); [European Parliament and Council, 2014](#); [US Department of Health and Human Services, 2016](#)). Recent collaborative initiatives should further stimulate development of both new and already existing drugs in neonates ([Davis and Turner, 2015](#); [International Neonatal Consortium, 2016](#)).

Neonatal Pain and Stress: Assessment and Management

RACHEL A. FLEISHMAN AND DENNIS E. MAYOCK

KEY POINTS

- Pain and discomfort in infants continue to be common occurrences in intensive care.
- Identification and management of neonatal pain remain challenging.
- Many neonatal pain scoring systems are available although most have not been validated in clinical practice.
- Untreated neonatal pain can result in long-term adverse outcomes such as alterations in brain structure and abnormal pain responses in childhood.
- Pharmacologic treatment of pain is widely used, but nonpharmacologic interventions may be as effective.
- Anesthesia for surgery remains concerning for potential adverse effects on the brain. New methods of neonatal pain recognition such as near-infrared spectroscopy and amplitude-integrated electroencephalography deserve further evaluation.

Relief of human suffering is one of the most important goals of all healthcare providers. Advances in neonatology have significantly reduced neonatal morbidity and mortality, but pain, discomfort, and stress remain sad realities for babies in the neonatal intensive care unit (NICU). Assessing, managing, and trying to limit these clinical realities, particularly while caring for critically ill neonates, remain challenging and increasingly controversial. Fortunately, considerable clinical and laboratory research and clinical dialogue continue to push neonatal providers toward best clinical practices in this problematic arena. This chapter describes the history, developmental biology, and public policies that have informed and shaped current clinical practices; it also summarizes relevant clinical and basic research regarding clinical assessment tools and both pharmacologic and nonpharmacologic management approaches. Finally, future directions in this field are suggested.

Historical Timeline

It is important to know the historical background of challenging medical issues so as to understand the imperatives for future directions. Management of neonatal pain and stress serves as an

excellent example of this philosophy. Thus a brief history of neonatal pain management follows:

- 1806: Morphine (named for Morpheus, Greek god of dreams) is isolated from the opium poppy by the pharmacist Friedrich Serturner.
- 1960s–1980s: Infants are believed to be too immature to feel pain; adverse effects of anesthetics are feared; the Liverpool method (pancuronium only, no anesthesia) is used widely for patent ductus arteriosus (PDA) ligation in premature infants.
- 1985: A landmark paper is published by [Anand et al. \(1985\)](#) describing adverse physiologic effects of the Liverpool method and improved outcomes with use of anesthesia for PDA ligation; anesthesia and postoperative pain medication begin to become more widely used in neonatal care.
- 1987: A joint statement is issued by the [American Academy of Pediatrics \(AAP\)](#) and the American Society of Anesthesiologists regarding the safety and efficacy of neonatal operative anesthesia and postoperative analgesia, regardless of age or maturity ([AAP, 1987](#)).
- 2000: The AAP and the Canadian Pediatric Society issue a joint statement regarding neonatal pain management directed at surgical anesthesia and postoperative and procedural pain assessment and relief ([Prevention and management of pain, 2000](#)).
- 2001: Neurodegeneration and behavioral deficits are reported in rodent pups following administration of general anesthetics, raising questions about their safety in human infants.
- 2003: The Joint Commission issues a mandate regarding pain assessment and management in all hospitalized patients, including neonates.
- 2004: The NEOPAIN trial (Neurologic Outcomes and Preemptive Analgesia in Neonates) results are published, concluding that preemptive morphine infusion did not improve outcomes in ventilated neonates and did not relieve procedural pain ([Anand et al., 2004](#)).
- 2006: Cerebral cortical activation is demonstrated following noxious stimuli in human infants despite lack of behavioral responses ([Slater et al., 2006](#)).
- 2009: More than 40 infant pain assessment tools are available around the world; most were developed for research and not validated for clinical use.

- 2010: Oral sucrose administration is found to decrease clinical pain scores in neonates but results in no changes in cortical activation (Slater et al., 2010).
- 2016: A well-controlled study demonstrates no difference in 2-year developmental outcomes after general versus regional anesthesia during neonatal surgery (Davidson et al., 2016).

Development of Public Policy

Since the late 1980s, in response to a public outcry regarding the recognition and management of pain in hospitalized patients, the US Department of Health and Human Services, the Joint Commission, and other professional organizations have promulgated mandates that dictate pain management practices for all patients, including neonates. The initial public policy statement regarding pain management for neonates undergoing surgical interventions was issued as a joint communication by the AAP Committee on Fetus and Newborn, Committee on Drugs, Section on Anesthesiology, and Section on Surgery and the American Society of Anesthesiologists (AAP, 1987). This statement strongly recommended that anesthesia and analgesia be given to neonates despite their age and cortical immaturity. The Acute Pain Management Guideline Panel of the US Agency for Health Care Policy and Research (Clinicians' quick reference guide, 1992) issued a second influential document unequivocally endorsing the need for pain management in neonates. These two documents helped initiate research studies addressing the recognition, prevention, and amelioration of neonatal pain.

The 2003 accreditation standards issued by the Joint Commission required healthcare providers to look across the continuum of life, including the neonatal period, at the complex nature of the pain experience so as to create new foundations for care without specifically providing instructions for assessing or managing neonatal pain. The subsequent conundrum was that neonatal caregivers were expected to assess and treat perceived neonatal pain and discomfort in the absence of evidence-based methods with which to base their assessment and therapy. Organizations commissioned interdisciplinary teams to incorporate regulatory directives and results of scientific investigation into institutional practice guidelines and standards for care (Anand and International Evidence-Based Group for Neonatal Pain, 2001; Howard et al., 2008a, 2008b; Lago et al., 2009). These guidelines include a patient's right to regular and systematic assessments of pain, interventions to relieve pain, evaluation of effectiveness of interventions, attention to long-term pain management needs, determination of the deleterious effects of unmanaged pain, and educational needs of families and staff members who provide care (Bell, 1994; Joint Commission, 2004; Howard et al., 2008a, 2008b; Lago et al., 2009).

As a result of these public policy initiatives and regulations, new tools for pain assessment and innovative methods to treat pain were developed and evaluated. Many questions remain unanswered, and new concerns have been raised. Neonates experience both acute and chronic pain. Treatment protocols for acute pain may not be appropriate for chronic pain, because the origin and resultant physiologic status can be quite different. A concrete result of these policies, guidelines, and interventions is the routine assessment and documentation of pain scores as a proxy for routine pain assessment for preterm and term neonates throughout their hospital stay. These scores, however, may not actually correlate with low pain exposure because of the prescribed way in which they are assigned (Rohan, 2014). Long-term use of narcotics and

other drugs leads to drug tolerance and the need for slow weaning to avoid drug withdrawal. The drugs themselves and drug tolerance and drug withdrawal may all contribute to adverse effects on brain development and neurodevelopmental outcomes.

Recent International Surveys of Clinical Practice

Nurses, physicians, and parents all play a front-line role in recognizing and ameliorating neonatal pain. The factors at play in determining the depth and breadth of pain assessment and treatment include nationality, level of education of bedside providers, use of clinical pain scales, time of day, and unit acuity. From surveys, nurses in Korea (Jeong et al., 2014) and Iran (Asadi-Noghabi et al., 2014) as well as physicians and nurses in southern India (Britto et al., 2014) routinely underestimate pain in neonates, do not acknowledge pain in neonates, and/or do not readily provide any type of analgesic measures for acute, procedural pain in neonates. When episodes of acute procedural pain were monitored in NICUs in Kenya, only 1 of 404 painful procedures had any form of analgesia, implying that more education is warranted to both recognize and treat neonatal procedural pain (Kyololo et al., 2014). In Spain, the types of routine pain assessments commonplace in US hospitals at the behest of the Joint Commission are not common. Many units did not routinely use clinical pain scales, and those that did used them inconsistently (Avila-Alvarez et al., 2015a). Despite the lack of pain scales, many intubated neonates in Spanish NICUs are receiving sedative infusions such as fentanyl and/or midazolam. The more regimented the unit in systematically assessing pain, the more likely it is that neonates receive these medications (Avila-Alvarez et al., 2015b). NICUs in France noted that painful procedures were more consistently ameliorated by analgesics during the morning hours than at other times of the day (Guedj et al., 2014). A survey of all physicians and nurses in seven UK NICUs reported that even though clinicians are knowledgeable about neonatal pain, there is still a large gap between knowledge and practice (Akuma and Jordan, 2012). Educational initiatives geared toward helping nurses understand and recognize pain can improve both bedside assessments and pain management (Aymar et al., 2014).

The EUROPEAN Pain Audit in Neonates (EUROPAIN) trial, completed in 2015, was a prospective trial involving a cohort of 6680 neonates enrolled in 243 NICUs in 18 European countries that cataloged demographics, methods of respiration, use of continuous or intermittent sedation, analgesia, or neuromuscular blockers, pain assessments, and drug withdrawal symptoms in the first 28 days of admission. Wide variations in practice were documented regarding documentation of pain scores, genres of respiratory support and their association with analgesia, and use of analgesia for any neonates receiving any modality of respiratory support. Surprisingly, despite awareness of the results of trials such as NEOPAIN (Anand et al., 2004), the median use of sedation or analgesia for intubated neonates was 89%, with 74% of these neonates receiving opioids, 25% receiving midazolam, and 25% receiving neuromuscular blockers as either a bolus (18%) or a continuous infusion (7%). The large, prospective nature of this study provides a compelling snapshot of how pain is assessed and how pharmacologic analgesia is prescribed to many neonates in the NICU (Carbajal et al., 2015).

Italy represents a unique example of the power of unified national guidelines and education. Surveys conducted in 2003 revealed that procedural pain in newborns was underestimated

or inadequately managed in Italian NICUs (Lago et al., 2005). Italian neonatologists accepted the remarkable challenge of drafting national pain guidelines, which were then implemented in 2005. Follow-up surveys conducted 5 years after adoption of these guidelines showed that most Italian NICUs provide some form of analgesia and sedation for invasive procedures, but their routine adherence to best practices for pain control and monitoring was not optimal (Lago et al., 2012, 2013). Despite tremendous efforts to increase awareness of and provide systematic approaches toward ameliorating pain, analgesia is not consistently reaching the bedside.

Knowledge translation and quality improvement activities are key research techniques available to adapt clinical practice to evidence-based recommendations. A focus group study (Stevens et al., 2011) conducted in three Canadian NICUs concluded that neonatal pain is managed most successfully when:

- There is a positive culture of interprofessional collaboration.
- Nurses are permitted to make decisions autonomously with regard to assessment and treatment of pain without interference from professional hierarchies.
- Patient conditions are less complicated.
- The NICUs are set up in a manner that facilitates analgesia by providing easy access to materials.
- NICUs have appropriate staffing, with time allowed for pain assessment and treatment.
- NICUs have a culture that emphasizes making time for analgesia.

An emphasis on uniform practice guidelines can also help. For example, implementing a neonatal pain and sedation protocol in two NICUs resulted in an increase in opiate prescription, an increase in pharmacologic interventions, and improved staff satisfaction without affecting the duration of mechanical ventilation, the length of intensive care stay, or adverse NICU (Deindl et al., 2013) or neurodevelopmental (Deindl et al., 2016) outcomes. Another example is a recent study demonstrating that a nursing-driven comfort protocol aimed at titrating morphine infusions on the basis of bedside pain scores decreased the use of morphine infusions solely for preemptive analgesia (Fleishman et al., 2015).

Ontogeny and Development of Pain and Stress Responses

The sensory system of the neonate, especially in the preterm neonate, is immature (Fig. 34.1). Afferent input from both noxious and nonnoxious stimuli terminates in the dorsal horn of the spinal cord in a diffuse manner on multiple cells, resulting in the infant's inability to distinguish between noxious and nonnoxious stimuli and limits the care provider's ability to correctly interpret the infant's behavioral response. In the neonatal rat, separation of sensory input is not completed until 3 to 4 weeks after birth (approximately 1 to 2 years in humans) (Beggs et al., 2002); this prevents the newborn from consistently differentiating touch from painful sensory input. The responses of the infant are therefore nonspecific. With repeated painful exposures, infants may lose any discriminatory ability and develop hypersensitive states for long periods. This hypersensitivity persists even if nonnoxious stimuli are introduced (Jennings and Fitzgerald, 1998). The responses are less synchronized in the immature central nervous system (CNS) because of underdeveloped myelination and slower synaptic transmission as manifested in longer and more variable latencies (Jennings and Fitzgerald, 1998; Fitzgerald, 2005).

Neuronal connections within the cortex appear to form at approximately 22 weeks' gestation (Kostovic et al., 2006), suggesting that higher cortical level pain processing may be limited despite the presence of a behavioral response (Fitzgerald and Walker, 2009). In addition, the neonate lacks sufficient descending modulatory control, thereby limiting its ability to benefit from endogenous control over noxious stimuli compared with adults (Fitzgerald and Koltzenburg, 1986; Hathway et al., 2006).

Neurophysiologic investigations have dramatically changed our understanding of nociception in the newborn. From use of research methods such as near-infrared spectroscopy (NIRS) and electroencephalography techniques such as amplitude-integrated electroencephalography, it is clear that cerebral cortical activation occurs with noxious stimulation, such as needle pokes, as early as 24 weeks' gestation. Moreover, cortical activation has been noted even in infants who manifest no behavioral response to a stimulus (Slater et al., 2006; Holsti and Grunau, 2007; Fitzgerald, 2015). The converse has also been noted in studies reporting that oral sucrose administration decreases clinical observational scores, with no changes noted in cortical activation from noxious stimulation (Slater et al., 2010; Stevens et al., 2013). Such findings raise the question that our patients may be perceiving pain at a cortical level despite our interventions (pharmacologic and nonpharmacologic) and that pain scoring tools may only provide limited information, possibly underestimating the pain response in neonates (Maxwell et al., 2013).

Noxious stimuli in adults result in the release of inflammatory and trophic factors that activate and sensitize nociceptors in the injured tissue. Such noxious stimuli lead to nociceptive afferent input to the CNS, exciting nociceptive circuits in the spinal cord, brainstem, thalamus, somatosensory cortex, cingulate cortex, and amygdale (Tracey and Mantyh, 2007; Woolf and Ma, 2007). However, noxious stimuli in infants do not evoke similar patterns of CNS activity. (Fitzgerald, 2005). The response to noxious stimuli is more diffuse and less spatially focused in infants. Studies in rats demonstrate major alterations in neuronal circuitry with maturation. These animal data may parallel developmental changes that have been noted in humans (Fitzgerald, 2005). Local tissue injury resulting from repeated heel sticks and invasive procedures triggers increased proliferation of nerve endings in surrounding tissues, particularly when this damage occurs early in gestation. As a result, scars (e.g., from heel sticks, old intravenous [IV] sites) and surrounding tissues can remain hypersensitive well beyond the neonatal period (Reynolds and Fitzgerald, 1995; Jennings and Fitzgerald, 1998).

In summary, the immature infant nervous system:

- Lacks the ability to discriminate consistently between noxious and nonnoxious stimuli, often reacting with similar behavior to a variety of stimuli
- Lacks the ability to modulate pain responses
- Does not consistently manifest signs or symptoms that allow care providers to accurately assess the infant's level of pain and discomfort

Assessment of Neonatal Pain and Stress

Assessment of the Neonatal Behavioral Responses to Pain

Tools for assessment of neonatal pain and stress must be based on an understanding of the normal development of behavioral responses to pain and stress—an infant is not a small adult. Behavioral

• **Fig. 34.1** 1, In early postnatal life, descending fibers are present, but inhibitory and excitatory influences are weak or absent. The connections gradually strengthen, becoming fully functional at the end of the third postnatal week. 2, A-fibers are the first primary afferents to enter the dorsal horn gray matter and are present during the last few embryonic days. Their distribution is diffuse, with exuberant, more superficial projections gradually retracting over the first three postnatal weeks. C-fibers are present in the dorsal horn during late embryonic stages but only enter the gray matter 2 to 3 days before birth. Unlike A-fibers, they project to topographically appropriate regions in lamina II of the spinal cord as soon as they enter. C-fiber synaptic connectivity is present, although weak at the time of birth, with connections strengthening over the first two postnatal weeks. 3, At birth most (approximately 80%) of the dorsal root ganglion neurons express the nerve growth factor receptor *trkA*. Over the first postnatal week, this population reduces, with approximately half of these neurons losing their *trkA* expression and beginning to express receptors for glial cell line-derived neurotrophic factor (identifiable as the isolectin B4-binding population). 4, The balance of excitation and inhibition in the superficial dorsal horn develops postnatally, through changes in both local interneuron circuitry and descending fibers. A-fiber input is stronger in the neonate and weakens as the influence of C-fiber input increases. 5, Primary afferent innervations of the skin occur earlier than central projections. By late embryonic stages, primary afferents of all classes have reached the skin and innervate through the dermis into the epidermis. These projections die back during the immediate perinatal period to leave the full adult situation of dermal innervations present soon after birth. *DRG*, Dorsal root ganglion; *IB4*, isolectin B4; *N52*, *trkA*+, nerve growth factor receptor *trkA*. (From Beggs S, Fitzgerald M. Development of peripheral and spinal nociceptive systems. In Anand KJ, Stevens BJ, McGrath PJ, eds. *Pain in Neonates and Infants*. 3rd ed. Philadelphia, PA: Elsevier; 2007:15.)

responses to noxious stimuli in infants are not always predictable because of immaturity of the CNS; therefore assessment of pain and response to therapeutic intervention can be similarly unpredictable. Significant structural and functional changes occur in pain pathways during development, and these continue after birth.

The lack of verbal skills, immature behaviors in response to pain, and the nonspecific nature of physiologic indicators of pain in a critically ill patient all combine to make accurately assessing pain in term and preterm neonates quite challenging. The challenge of pain assessment is further compounded by typical NICU interventions such as mechanical ventilation, physical restraints,

and pharmacologic sedation, all of which mask distress behaviors (Maxwell et al., 2013). Because the gold standard of pain assessment (self-reporting using validated scales) is not applicable to neonatal patients, providers must rely on physiologic, behavioral, and biobehavioral indicators as a surrogate for self-reporting pain (Maxwell et al., 2013).

Infant Pain Scores

Multiple neonatal pain scoring tools integrate physiologic, behavioral, and biobehavioral indicators into a pain score. These tools

assess the response to noxious stimuli by categorizing the behavioral or physiologic reactions of the infant or a combination of both (Grunau and Craig, 1987). The behavioral responses can include limb movements, muscle tone, crying, and characteristic facial expressions. Crying is the least reliable indicator of neonatal pain (Grunau and Craig, 1987; Guinsburg et al., 1998; Stevens et al., 1993). The physiologic measures can include heart rate, oxygen saturation, and respiratory rate. Specific facial expression changes are believed to be the most reliable indicators of pain (brow bulge, eye squeeze, nasolabial furrow, taut lips, and open mouth); see Fig. 34.2 for examples of these characteristic facial changes. Use of facial expression changes can be challenging when the infant's face is partially covered with adhesives used to secure tubes and lines or with a phototherapy mask in place.

More than 40 discrete scoring tools exist to assess pain in neonates, many validated only for research studies (Ranger et al., 2007). Scoring tools that provide a multidimensional assessment of pain are preferred clinical tools; some tools lack sensitivity and specificity by relying, for example, only on changes in vital signs (Raeside, 2011). Some recent publications list currently available neonatal pain assessment tools (Maxwell et al., 2013; Committee on Fetus and Newborn and Section on Anesthesiology and Pain Medicine, 2016). Only five neonatal pain scales have undergone rigorous psychometric testing with patients serving as their own controls:

- Neonatal Facial Coding System
- Premature Infant Pain Profile (PIPP)
- Neonatal Pain and Sedation Scale
- Behavioral Infant Pain Profile
- Douleur Aiguë du Nouveau-né

The PIPP scale is one of the most commonly used and well-validated scales; a review of 62 studies of the PIPP score over 13 years reinforced this scoring measure as valid, reliable, and clinically feasible and useful at measuring acute procedural or postoperative pain (Stevens et al., 2010), with strength lying in a composite (measuring behavioral and physiologic indicators) approach. In 2014, researchers refined the scoring tool further, termed the PIPP-Revised score, to better encompass markers of pain and distress across the spectrum of gestational age (Stevens et al., 2014).

It would be ideal to use a neonatal pain scoring tool that best matches the anticipated type of pain that an infant may experience (acute procedural, postoperative, chronic pain). For example, a

prospective comparison of multiple pain scores in neonates after cardiac surgery demonstrated a scoring tool called the COMFORT (Maaskant et al., 2016) score most accurately correlated with pain and analgesic response in those patients (Franck et al., 2011b). Another specific example is noted with a validated scoring tool called the Echelle Doleur Inconfort Nouveau-Né (EDIN) developed specifically to assess prolonged pain in preterm infants (Debillon et al., 2001). That said, it is difficult to train and maintain provider skills in the use of multiple scoring tools. Determining which scoring tool best matches local patient composition allows care providers to become expert in using a single tool or two tools.

A common conundrum is that providers find themselves treating chronic pain related to complications of intensive care using tools designed and validated for acute, procedural, and/or postoperative pain (van Ganzewinkel et al., 2014). Few publications in the literature attempt to define chronic pain (and/or stress) in the newborn, leaving it to be measured with tools best validated and studied for measuring acute procedural pain. In 2014, researchers conducted an international survey of experts in neonatal pain, including physicians, nurses, researchers, and parents from around the world, and then used the Delphi method to propose a definition of chronic pain in the neonate. They put forth the following (van Ganzewinkel et al., 2014): "Chronic pain can often not be associated with a specific cause. It has no obvious endpoint in sight and is no longer proximate to an event or procedure. Chronic pain may alter perception causing nonnoxious events to be perceived as painful, leading to a chronic pain response. It depletes stress hormones, increases energy consumption, and therefore interferes with growth. As a consequence, chronic pain may likely prolong hospitalization and worsen or add to existing neonatal morbidities."

According to Allegaert et al. (2009), the optimal approach to neonatal pain management should include:

- Reducing the frequency of painful procedures
- Reducing environmental stressors
- Facilitating neurologic development
- Determining the best technique to minimize the pain and stress associated with procedures
- Delegating responsibility for pain assessment and treatment to the bedside nursing staff
- Using a balanced multimodal approach to pain control

The involvement of parents in managing their own child's pain is also important; parents randomized to receive a pain information booklet were better prepared to understand infant pain cues and comforting techniques and took more active roles in infant pain care while the infant was hospitalized (Franck et al., 2011a, 2012).

Bedside Noninvasive Neurophysiologic Measures to Evaluate Pain and Stress

Several additional modalities may help healthcare providers recognize pain in neonates. NIRS might be one of those. In a study of 29 infants of between 26 and 36 weeks' gestation at birth, cortical activation occurred over both somatosensory cortices during both unilateral tactile and painful stimulation (Bartocci et al., 2006). Cortical hemodynamic activity changes in response to noxious stimuli measured by NIRS were found to have an excellent correlation to the PIPP score (Slater et al., 2008). Amplitude-integrated electroencephalography also can be used to detect cortical activation in neonates (Toet and Lemmers, 2009). These and other new technologies will be needed to first recognize and then continually assess and manage pain and discomfort in our fragile patients.

• **Fig. 34.2** Facial Expressions of Physical Distress and Pain in the Infant. (Modified from Wong and Wilson's *Clinical Manual of Pediatric Nursing*, 5th ed.)

Long-Term Consequences of Neonatal Pain and Stress

Untreated pain and stress experienced during the neonatal period are linked to adverse long-term outcomes (Anand and Hickey, 1987; Abdulkader et al., 2008). The acute physiologic responses to pain (elevations of the levels of cortisol, catecholamines, and lactate, hypertension, tachycardia, respiratory instability, glucose instability, and changes in cerebral blood flow) affect developing organs, especially the brain. Exposure to pain and painful procedures is often directly related to the acuity of the hospitalization, so studies evaluating a direct relationship between pain and outcomes must be adjusted for multiple clinical confounders.

Data suggest that, with rigorous controls and statistics, structural changes on magnetic resonance imaging (MRI) at both term-corrected age (Zwicker et al., 2013) and 7 years of age (Ranger et al., 2015) may be related to increased exposure to pain. Untreated pain in the NICU is also associated with altered pain perception of subsequent immunizations after circumcision without anesthesia (Taddio et al., 1997; Grunau et al., 2007), abnormal cortisol responses to stress in later infancy (Grunau et al., 2007) and at school age (Brummelte et al., 2015), and altered pain responses in childhood (Grunau et al., 1998). Higher numbers of skin-breaking procedures from birth to term-corrected gestation predict lower cognitive and motor development indices of Bayley Scales of Infant Development at 8 and 18 months, after early illness severity, overall morphine exposure, and number of days of postnatal dexamethasone administration have been controlled for (Grunau et al., 2009). Greater neonatal pain exposure is also associated with lower body weight percentiles at 32 weeks' corrected gestation after adjustment for appropriate confounders (Vinall et al., 2012). There is concern that such hormonal changes might lead to the development of cardiovascular disease and type 2 diabetes in adulthood (Rosmond and Bjornorp, 2000; Kajantie et al., 2002).

Chronic pain can affect growth, immune function, recovery, and length of hospitalization. In addition, a growing body of evidence has drawn attention to the potential deleterious effects of repeated handling, stress, and pain on long-term memory, social and cognitive development, and neural plasticity (Anand and Hickey, 1987; Anand and Carr, 1989; Pokela, 1994; Taddio et al., 1995a; Anand, 1998; Jennings and Fitzgerald, 1998; Porter et al., 1999).

Clinical Pain and Stress Management Strategies

Surgical Anesthesia

The recognition that infants who undergo surgical interventions experience dramatic physiologic and metabolic changes, similar to those noted in adults, with significant pain has changed current practice. It is well recognized that infants perceive pain, and surgical intervention without anesthesia and analgesia leads to increased morbidity and excess mortality; however, experience obtained in older children and adults cannot be extrapolated to immature patients. Providing general anesthesia for neonates requires an intimate knowledge of the developmental status and function of each organ system. A complete review of this subject is beyond the scope of this chapter. Interested readers are referred to *A Practice of Anesthesia for Infants and Children* by Cote and Lerman (2013) or *Smith's Anesthesia for Infants and Children* by Davis et al. (2011).

Fetal Surgery

The fetus has increasingly become a candidate for surgical intervention to repair fetal anomalies such as congenital cystic adenomatoid malformation of the lung, sacroccygeal teratoma, congenital diaphragmatic hernia, and myelomeningocele and to treat fetal disorders such as severe anemia secondary to hemolytic diseases. Many fetal interventions are performed with general maternal anesthesia, which also provides fetal anesthesia, but certain procedures are attempted only with maternal analgesia and local anesthesia. Thus during those fetal surgical interventions, the fetus requires consideration for pain management to attenuate fetal physiologic and hormonal stress responses (Giannakouloupoulos et al., 1999; Fisk et al., 2001). Anand and Hickey (1987) summarized the available evidence regarding fetal and neonatal nociceptive activity and put all care providers on notice that late-gestation fetuses and newborns have intact cortical and subcortical centers necessary for pain perception and demonstrate physiologic responses to painful stimuli similar to those in adults. A review of the literature supports the contention that the fetus perceives pain (Lee et al., 2005; Brusseau, 2013). However, fetal anesthesia is not without risk. Fetal exposure to opioids may result in smaller brain volumes in the neonate (Yuan et al., 2014).

Neonatal Surgery

Selection of anesthetic agents for neonates must account for the developmental status and function of each organ system and the potential adverse and toxic effects of specific anesthetic agents. Animal models suggest that anesthetic agents can be both neurotoxic and neuroprotective in the immature brain. Frequently used anesthetics act by two principal mechanisms, either by decreasing excitation via *N*-methyl-D-aspartate receptors (e.g., ketamine, nitrous oxide) or by increasing inhibition via γ -aminobutyric acid receptors (e.g., benzodiazepines, barbiturates, propofol, etomidate, isoflurane, enflurane, halothane). In the immature rat brain, drugs that act by either of these two mechanisms can induce widespread neuronal apoptosis and abnormal synaptic development (Ikonomidou et al., 1999; Ishimaru et al., 1999).

The applicability of these findings to the human infant undergoing surgery has been questioned (Soriano and Anand, 2005). Some authors suggested that toxicity may occur in human infants (Wilder et al., 2009), but limitations in study design and data collection have precluded most investigations from proving causation. Moreover, the available data are conflicting (Kalkman et al., 2009; Hansen et al., 2011; Sprung et al., 2012). The US Food and Drug Administration (FDA) reviewed available information in 2007 and again in 2011 and concluded that no change in clinical practice was justified (Mellon et al., 2007; Rappaport et al., 2011). Recent work questions the association between anesthesia and abnormal neurodevelopmental outcomes in human infants (Davidson et al., 2016; Sun et al., 2016). Further answers should be forthcoming as the SmartTots initiative (joint effort of the International Anesthesia Research Society and the FDA) and the Pediatric Anesthesia and Neurodevelopment Assessment project publish results of their ongoing studies.

Regional anesthesia for neonatal surgery is commonly used for minor interventions. As more experience with regional anesthesia for major surgical procedures is gained, such practice is expanding. The advantages of regional anesthesia may include less postoperative apnea, less need for intubation, and better postoperative pain

control. [Bosenberg and Flick \(2013\)](#) reviewed the risks and benefits of regional anesthesia in the neonate in depth.

Postoperative Pain Management Strategies

Pain management after surgical intervention, like acute pain management, requires knowledge of the developmental status and function of end-organ systems and the potential adverse and toxic effects of specific analgesic agents. Unfortunately, the current body of neonatal pain literature focuses heavily on procedural pain management and lacks systematic data on acute perioperative pain management in the neonate ([Maitra et al., 2014](#)). The Association of Pediatric Anesthetists of Great Britain and Ireland commissioned guideline development for pain management after surgery and painful medical procedures with graded recommendations to allow better interpretation ([Howard et al., 2008a, 2008b](#)). These guidelines provide evidence-based recommendations and list best clinical practice points when published evidence is insufficient to make formal recommendations. In the developing world, if infants survive the challenges of both diagnosis and surgery for their congenital anomalies, postoperative pain is often not considered or is under-managed ([Mathew et al., 2011](#)).

[Taylor et al. \(2006\)](#) surveyed 10 NICUs regarding their postoperative pain assessment and management practices; they found that pain assessment documentation was extremely variable. Nursing documentation was performed for most infants, whereas few physicians documented any assessment. Most infants were treated with opioids, benzodiazepines, or both, and some infants (7%) received no analgesia despite recent major surgery. [Van der Marel et al. \(2007\)](#) evaluated the use of rectally administered acetaminophen as an adjuvant treatment with regard to continuous morphine infusion in postoperative neonates but could not demonstrate any additional analgesia effect. On the basis of the monitoring of pain scale data, neonates likely require significantly less morphine to control pain and discomfort than older infants do. [Bouwmeester et al. \(2003a, 2003b\)](#) determined that neonates required less morphine for postoperative pain control and that the dose requirement increased with age. Both studies found that morphine was equally effective whether given by bolus or given by continuous infusion.

Many neonates remain intubated for mechanical ventilation after major surgery. Analgesia can be provided via IV administration of an analgesic agent, either by intermittent bolus dosing or by continuous infusion. Epidurals are undoubtedly effective in treating postoperative pain and alleviating unwanted side effects of systemic opioids in adults and older children. While the literature does support the benefits of epidurals for perioperative pain control for term and preterm neonates ([Bosenberg and Flick, 2013](#)), there is concern that the risk of placing thoracic epidurals by physicians without sufficient experience exposes neonates to the possibility of catastrophic neurologic outcomes ([Bosenberg et al., 2011](#)). In a study of infants younger than 6 months who required thoracotomy for congenital pulmonary malformations, those randomized to receive epidural anesthesia had a shorter time to full feedings and reduced intensity of postoperative care when compared with those randomized to receive systemic analgesia ([Di Pede et al., 2014](#)). Regional anesthesia, when used alone, may also reduce the incidence of postoperative apnea in preterm infants ([Craven et al., 2003](#)). A study of parent-controlled and nurse-controlled analgesia as an alternative to continuous opioid infusion for pain management in postsurgical infants in the NICU provides promising data that parent-controlled and nurse-controlled analgesia may provide more

individualized care and may potentially reduce opioid consumption ([Czarnecki et al., 2014](#)).

Mechanical Ventilation

The use of mechanical ventilation in neonates with respiratory failure is a common practice, although less so than in the past 3 decades. In older children and adults who require mechanical ventilation, sedation is routinely provided—most often with opiates ([Gélinas et al., 2004](#)). Extrapolation of evidence from studies in adult patients is what initially led to the routine use of opiate sedation in neonates during mechanical ventilation ([Kahn et al., 1998](#)), despite limited information regarding safety and efficacy in neonates ([Simons et al., 2003](#); [Anand et al., 2004](#)). The ability to assess and treat neonatal discomfort and pain is limited, and preemptive use of pharmacologic sedation during mechanical ventilation in newborns, especially preterm infants, was—and still is—controversial ([Anand and Hall, 2007](#)).

Mechanical ventilation in neonates is associated with an increase in hormonal stress responses, including increased cortisol and catecholamine levels ([Guinsburg et al., 1998](#); [Quinn et al., 1998](#)). In the past, infants who appeared uncomfortable while ventilated demonstrated asynchronous respiratory effort (i.e., “fighting the ventilator”), compromised gas exchange, and altered stress responses ([Dyke et al., 1995](#)). Pain and stress in newborns receiving mechanical ventilation were associated with decreased pulmonary compliance, atelectasis, and intrapulmonary shunting ([Bolivar et al., 1995](#)). However, with the introduction and use of surfactant replacement therapy, noninvasive ventilatory support, and synchronized ventilation, many of these problems associated with fighting the ventilator have been eliminated ([Quinn et al., 1993](#); [Claure and Bancalari, 2009](#); [Keszler, 2009](#)).

A randomized double-blind, placebo-controlled clinical trial of almost 900 neonates (NEOPAIN) reported no beneficial effect of preemptive morphine infusions in ventilated preterm infants and an increased incidence of severe intraventricular hemorrhage in preterm infants born at 27 to 29 weeks' gestation receiving preemptive morphine ([Anand et al., 2004](#)). A parallel study conducted by [Simons et al. \(2003\)](#) randomized 150 ventilated neonates to lower-dose preemptive analgesia with morphine. This study also failed to find any benefit of empiric morphine analgesia and did not recommend this practice ([Simons et al., 2003](#)). Secondary analysis of the NEOPAIN trial found that morphine infusions were independently associated with increased risk of air leak and a longer requirement for ventilatory support ([Bhandari et al., 2005](#)) as well as longer time to reach full-volume enteral feedings ([Menon et al., 2008](#)). Neither this trial nor the smaller pilot trials that preceded it ([Orsini et al., 1996](#); [Anand et al., 1999](#)) provided evidence that routine narcotic sedation during mechanical ventilatory support in neonates is beneficial. A subsequent trial conducted in 2013 randomized premature neonates to receive continuous infusion of fentanyl or placebo. Similarly to prior trials of morphine, the results demonstrated increased duration of mechanical ventilation and no decrease in prolonged pain, as measured by the EDIN algometric scale, for the treatment group. Continuous fentanyl infusion did reduce acute pain scores, measured via PIPP scores, and had fewer side effects when compared with open-label fentanyl boluses. The authors concluded that, just like morphine, “there is no place for the routine use of continuous fentanyl infusion in ventilated preterm newborns because of a lack of continued pain score reduction and increased side effects of continuous infusion

compared with the bolus administration of fentanyl” (Ancora et al., 2013).

A Cochrane review evaluated the effects of opioid analgesics on pain, duration of mechanical ventilation, mortality, growth, and development in neonates requiring mechanical ventilation (Bellú et al., 2008). No differences in mortality, duration of mechanical ventilation, and short-term and long-term neurodevelopmental outcomes were found. If morphine sedation prolongs ventilatory support needs and the time to full enteral feeds, then an increase in the risk of complications related to the use of IV lines (bloodstream infections) and parenteral nutrition (cholestasis) should be expected (Menon and McIntosh, 2008). Hällström et al. (2003) studied risk factors for necrotizing enterocolitis in premature infants and found that the duration of morphine use was the strongest predictor for development of severe necrotizing enterocolitis. The Cochrane review concluded that “there is insufficient evidence to recommend routine use of opioids in mechanically ventilated newborns” (Bellú et al., 2008). Menon and McIntosh (2008) came to a similar conclusion in their review.

Procedures

Infants undergoing intensive care endure many painful procedures, often several times each day. Positive correlations between clinical pain scores and malondialdehyde, a marker for oxidative stress, suggest a significant relationship between procedural pain and oxidative stress in preterm neonates (Slater et al., 2012). The mode of delivery may alter acute pain response in term neonates, with those born vaginally having higher saliva cortisol levels and clinical pain response than those born by cesarean delivery (Schuller et al., 2012). Healthy term neonates who are sleeping or drowsy have decreased pain scores and a shorter duration of crying compared with awake term neonates when exposed to a painful stimulus (Mathai et al., 2011). Both pharmacologic and nonpharmacologic treatment strategies can decrease or completely relieve procedural pain and stress. Nonpharmacologic strategies including, but not limited to, sucrose administration, breastfeeding, nonnutritive sucking, sensorial saturation, and skin-to-skin care can be adapted for many procedures. These strategies are discussed later in Nonpharmacologic Analgesia.

Blood Sampling and Monitoring

Heel sticks are routinely performed to obtain blood samples from neonates. The most appropriate method for relieving pain from a heel stick has yet to be determined. The heel should be warmed to aid blood sampling. EMLA cream (eutectic mixture of local anesthetics) does not relieve the pain of a heel lance (Taddio et al., 1998; Stevens et al., 1999). Shah et al. (1997) and Larsson et al. (1998a, 1998b) demonstrated that neonates experiencing venipuncture had lower pain scores than those who underwent heel stick for blood sampling. In select neonates, venipuncture should be used preferentially over heel stick. Multiple studies have concluded that acetaminophen alone does not reduce the pain from heel lance (Ohlsson and Shah, 2015a).

Various nonpharmacologic interventions work well at decreasing pain associated with heel lance. A prospective study comparing the effect of fentanyl, facilitated tucking, and sensorial saturation on both clinical pain scores and cytokine markers of stress concluded that both fentanyl and sensorial saturation were efficacious at decreasing pain and stress from heel lance (Gitto et al., 2012). A Cochrane review of 19 studies including 1594 infants found

skin-to-skin care, often termed *kangaroo care*, to be effective at decreasing composite pain indicators for single painful procedures such as heel lance (Johnston et al., 2014).

Tracheal Intubation

Premedication before tracheal intubation facilitates the procedure, treats pain, and prevents bradycardia, tachycardia, and increased intracranial pressure in the newborn. In 2010 the AAP issued a policy statement with grade A evidence-based recommendations that all newborns should receive analgesic premedication for endotracheal intubation except for emergency intubations during resuscitation or newborns in whom instrumentation of the airway is likely to be extremely difficult (Kumar et al., 2010; Barrington, 2011). A key component of premedication is analgesia.

Premedication for intubation is not yet common practice in the NICU. International assessments of clinical practice continue to affirm nonuniform compliance with recommendations for periprocedural analgesia (Sarkar et al., 2006; Whyte et al., 2000; Wheeler et al., 2012). Concerns about rapid medication availability, ability to maintain the airway, and the ability to provide ongoing ventilatory support continue to cause controversy (Carbajal et al., 2007). The frequency with which neonatal providers use premedication for nonemergent intubation internationally is unknown. Debate about the best medication regimen is ongoing in the literature, particularly surrounding the INTubation - SURfactant - Extubation (INSURE) procedure, which involves intubation to administer surfactant, with subsequent rapid extubation to positive pressure (de Kort et al., 2013), the concern being that sedation for intubation may make rapid extubation more challenging.

Once the decision has been made to premedicate the patient, the next question is which medications to use. Atropine at 0.02 mg/kg IV or intramuscularly with no minimum dosage has a grade A evidence-based recommendation for its effects as a vagolytic (Kumar et al., 2010; Barrington, 2011). A rapid-acting analgesic agent should also be given; the current best choice is fentanyl, a fast-acting opioid, as morphine has been shown to be no better than placebo in randomized trials because of its slow onset of action (Kumar et al., 2010; Barrington, 2011). Remifentanyl, a short-acting opioid with extremely rapid onset and short half-life, is also an acceptable option for analgesia (Badiie et al., 2013; Avino et al., 2014). Rapid-onset muscle relaxants also carry grade A evidence-based recommendations for the ability to facilitate the procedure; however, many providers have concerns about removing spontaneous respiratory drive. Propofol, an anesthetic that provides no analgesia, may be an appropriate substitute for the combination of atropine and a muscle relaxant. The advantages of propofol may include continued spontaneous breathing during the intubation procedure. This tremendous advantage should be weighed against the uncertain pharmacokinetics and duration of action as well as minimal experience with this medication in neonates. In addition, there is the risk of pain when it is injected into small veins, with extreme pain if it extravasates (Barrington, 2011). Midazolam, a sedative, is contraindicated when preterm neonates are being intubated, as it has been associated with adverse events in a small prospective, randomized controlled trial (Kumar et al., 2010).

Circumcision

Neonatal male circumcision is the most common pediatric surgical procedure, with rates ranging from 42% to 80% of males depending on the country (Simpson et al., 2014). In 2012 the AAP

circumcision policy statement (AAP Task Force on Circumcision, 2012) not only affirmed the benefits of circumcision but unequivocally stated that analgesia must be provided during neonatal circumcision. Adequate analgesia means having a trained provider perform the procedure and provide pharmacologic analgesia (Task Force on Circumcision, 2012). Application of EMLA cream, a topical anesthetic, dorsal penile nerve block, which provides local analgesia, and subcutaneous ring block, which also provides local analgesia, are each evidence-based methods of pharmacologic analgesia. However, anesthesiologists argue that EMLA cream may be insufficient (Paix and Peterson, 2012). Subcutaneous ring block has been found to be more effective than EMLA cream or dorsal penile nerve block (Taddio, 2001). Nonpharmacologic techniques such as positioning or sucrose pacifiers, used alone, are not an acceptable alternative for pain control.

A randomized clinical trial assessing neonatal circumcision pain with a Gomco versus a Mogen clamp, performed in 251 infants, concluded that the Mogen clamp is associated with less physiologic signs of pain (lower heart rate, blood pressure, and salivary cortisol responses) but with no difference in Crying - Requires oxygen - Increased vital signs - Expression - Sleepless (CRIES) pain scores (Sinkey et al., 2015).

Other Invasive Procedures

Placement of a central venous catheter requires topical anesthesia with EMLA cream or infiltration of the skin with lidocaine. In addition, a parenteral opioid, such as morphine or fentanyl, is typically required (Taddio et al., 2006). Consideration should also be given to regional blocks, if technically feasible, for central line placement.

The pain of a lumbar puncture is compounded by both the needle puncture and the distress caused by the body position required for the procedure. EMLA cream has been shown to decrease the pain of lumbar puncture in children (Halperin et al., 1989). Fentanyl does decrease the pain of lumbar puncture, with the caveat that it can cause respiratory depression (Fallah et al., 2016).

Chest tube insertion requires an IV opioid, adequate local analgesia (lidocaine), or both.

Pharmacologic Analgesia

The severity of the pain, its cause, available administration routes, and potential side effects should all be considered during selection of an analgesic. Once medication administration has begun, careful monitoring for efficacy and side effects can decrease the risk of potential adverse events. A key component of effective pain management is continued reassessment after each intervention is introduced, although this is difficult to do with limited pain assessment tools.

Nonopioid Analgesics

Nonsteroidal Antiinflammatory Drugs (Indomethacin, Ibuprofen, Ketorolac)

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandin synthesis by inhibiting the action of cyclooxygenases that are responsible for the breakdown of arachidonic acid to prostaglandins. Prostaglandins are part of the mechanism of local inflammatory response that results in pain; by inhibiting prostaglandin synthesis, NSAIDs are then able to inhibit pain. NSAIDs have many adverse physiologic and developmental effects, including sleep cycle disruption, increased risk of pulmonary hypertension,

cerebral blood flow alterations, decreased renal function by decreasing glomerular filtration rate (Allegaert et al., 2008), alteration in thermoregulatory control, and changes in platelet function. Development of the CNS, cardiovascular, and renal systems depends on prostaglandins, so these potential adverse effects are particularly worrisome for neonates and infants. Newborns younger than 21 days of age and less than 37 weeks' corrected gestational age were more likely to have bleeding events when given ketorolac for treatment of postoperative pain than older, maturer infants younger than 3 months of age in a retrospective review (Aldrink et al., 2011).

Acetaminophen

Acetaminophen is the most widely administered analgesic in patients of all ages. It inhibits the activity of cyclooxygenase in the CNS, decreasing the production of prostaglandins and peripherally blocking pain impulse generation (Arana et al., 2001). Neonates are able to form the metabolite that results in hepatocellular damage (Arana et al., 2001); however, it is not necessary to withhold acetaminophen therapy in newborns because of concerns of liver toxicity. In fact, the immaturity of the newborn's cytochrome P450 system may actually decrease the potential for toxicity by reducing production of toxic metabolites (Collins, 1981).

Pharmacodynamic and pharmacokinetic studies of acetaminophen in infants recommend less frequent enteral dosing intervals of acetaminophen (every 8 to 12 hours in preterm and term neonates) because of slower clearance times and higher rectal dosing because of decreased absorption (van Lingen et al., 1999; Arana et al., 2001; van der Marel, 2003). Rectally administered acetaminophen has a longer half-life, but absorption is highly variable because it depends on the individual infant and the placement of the suppository. It should also be noted that the suppository may contain the entire drug in its tip and should be divided lengthwise if a partial dose is desired. IV acetaminophen has become available in recent years, with dosing recommendations that lack validated pharmacokinetic or pharmacodynamic correlates (Allegaert et al., 2011). While rectally administered acetaminophen does not appear to decrease narcotic needs (van der Marel, 2007), IV paracetamol can decrease the need for morphine analgesia in preterm infants (Harma et al., 2016).

A 2015 Cochrane review emphasized that acetaminophen "does not significantly reduce pain associated with heel lance or eye examinations. [Acetaminophen] given after assisted vaginal birth may increase the response to later painful exposures. [Acetaminophen] should not be used for painful procedures given its lack of efficacy and its potential for adverse effects. [Acetaminophen] may reduce the total need for morphine following major surgery" (Ohlsson and Shah, 2015a).

Epidemiologic data suggest a link between perinatal acetaminophen exposure and an increased risk of developing asthma (Cheelo et al., 2015) and autism (Bauer and Kriebel, 2013; Ohlsson and Shah, 2015b; Andrade, 2016). While the association between acetaminophen and autism correlates with maternal use during pregnancy, the association with asthma is strongest with acetaminophen use in infancy. As with all epidemiology studies, causation is difficult to ascertain.

Opioid Analgesics

Opioids are believed to provide the most effective treatment for moderate to severe pain in patients of all ages, but there is a wide range of interpatient pharmacokinetic variability. Opioid dosing depends on the severity of the pain as well as the age and clinical

condition of the infant. One group of investigators suggested that opioids should be used in infants younger than 2 months only in a monitored setting such as an intensive or intermediate care unit (Yaster et al., 2003). Others have proposed a less conservative recommendation, restricting the use of opioids to monitored settings for any infant younger than 6 months.

Morphine

Morphine remains the gold standard opioid, used for pharmacologic pain treatment in neonates, although not necessarily because it has been shown to be the most effective. It is derived from the opium poppy and is metabolized in the liver by uridine diphosphate glucuronyltransferase into two active metabolites: (1) morphine 6-glucuronide (M6G), a potent opiate receptor agonist, and (2) morphine 3-glucuronide (M3G), a potent opiate receptor antagonist. Both metabolites and some unchanged morphine are excreted in the urine. The predominant metabolite in preterm and term neonates is M3G. Because of slow renal excretion, both metabolites can accumulate substantially over time, especially M3G (Saarenmaa et al., 2000; Bouwmeester et al., 2003a, 2003b). There is thus the potential for late respiratory depression because of a delayed release of morphine from less well-perfused tissues and the sedating properties of the active M6G metabolite.

Use of the lowest dose possible to achieve the needed analgesia is advised because the predominant metabolite of morphine in infants is M3G, a potent opiate receptor antagonist. Escalating morphine doses will also increase the levels of M3G in the infant, interfering with the goal of adequate analgesia. Dosages as low as 1 to 5 $\mu\text{g/kg}$ per hour can provide adequate analgesia, minimizing the risk of accumulation of high M3G levels, given that metabolite's prolonged half-life (Bouwmeester et al., 2003a, 2003b).

Clearance or elimination of morphine and other opioids is prolonged in infants, because of the immaturity of the cytochrome P450 system. The rate of elimination and clearance of morphine in infants 6 months or older approach that of adults. Chronologic age seems a better indicator than gestational age of how well an infant metabolizes opioids (Scott et al., 1999).

Infants are at greater risk of opioid-associated respiratory depression because of their immature respiratory control mechanisms. There is an increase in the levels of unbound or free morphine and M6G available to reach the brain as a result of the reduced concentration of albumin and α_1 -acid glycoproteins (Houck, 1998).

Hypotension, bradycardia, and flushing constitute the response to the histamine release associated with rapid IV administration of morphine. Histamine release may cause bronchospasm in infants with chronic lung disease, although this is not commonly seen. Morphine sedation may result in extended need for ventilatory support in neonates (Anand et al., 1999; Bhandari et al., 2005).

Dosing recommendations currently reflect the wide range of interpatient pharmacokinetic variability. In the past, an IV morphine dose of 0.03 mg/kg was suggested as a starting dose in infants not receiving mechanical ventilation, whereas an IV morphine dose of 0.05 to 0.1 mg/kg was recommended as an appropriate starting dose in infants on ventilators. Significantly lower doses are now recommended (Lynn et al., 2000; Saarenmaa et al., 2000; Bouwmeester et al., 2003a, 2003b, 2004; Anand et al., 2008). Titration to the desired clinical effect is done by adjustment of both the dose and the frequency of administration while the needs and responses are continually being assessed (Allegaert et al., 2009). As the use of morphine for analgesia and sedation in neonates is explored further, it is becoming clear that some of the risks may outweigh the potential benefits (Ng et al., 2003; Nandi et al.,

2004; Carbajal et al., 2005; Ranger et al., 2007; Anand et al., 2008; Black et al., 2008; Allegaert et al., 2009).

Fentanyl

Fentanyl is 80-fold to 100-fold more potent than morphine and causes less histamine release, making it potentially a better choice for infants with hypovolemia, hemodynamic instability, or congenital heart disease. Another clinical advantage of fentanyl is its ability to reduce pulmonary vascular resistance, which can be of benefit for infants who have undergone cardiac surgery, have persistent pulmonary hypertension, or need extracorporeal life support. Bolus doses of fentanyl must be administered over a minimum of 3 to 5 minutes to avoid chest wall rigidity, a serious side effect observed after rapid infusion. This adverse effect is treatable with naloxone or a muscle relaxant.

Fentanyl is highly lipophilic. It has a quick onset and relatively short duration of action, so it is typically used as a continuous infusion for treatment of postoperative pain. In infants aged 3 to 12 months, total body clearance of fentanyl is greater than that of older children, and the elimination half-life is longer because of its increased volume of distribution (Singleton et al., 1987). Fentanyl has an even more prolonged elimination half-life in infants with increased abdominal pressure (Koehntop et al., 1986; Gauntlett et al., 1988). Because of tachyphylaxis, continuous infusions of fentanyl are often increased to maintain constant levels of sedation and pain management. Infusion dosing can reach substantial levels, which then requires a prolonged withdrawal period.

A rebound transient increase in plasma fentanyl levels is a phenomenon known to occur after discontinuation of therapy in neonates. It is a result of the accumulation of fentanyl in fatty tissues, which can prolong its effects after continued use; therefore caution must be exercised in the use of repeated doses or continuous infusions.

Enterally Dosed Opioids

Methadone is used in infants, primarily in the context of withdrawal from either maternal narcotic use or long-term narcotic use in the NICU. The limited data regarding its efficacy and pharmacokinetics in this population suggest no dosing modifications are needed from those recommended for adults (Suresh and Anand, 1998; Chana and Anand, 2001; Ward et al., 2014). The respiratory depressant effect of methadone is longer than its analgesic effect; it is metabolized slowly and has a long half-life.

Codeine use in any pediatric patient is not recommended because of safety concerns (Andrzejowski and Carroll, 2016). No data are available regarding its effectiveness in neonates, and its use in this population is discouraged. Acetaminophen and codeine can be administered in a set formula, consisting of acetaminophen (120 mg) and codeine phosphate (12 mg per 5 mL) with alcohol (7%). The dose prescribed is limited by both the appropriate dose of codeine and the safe dose of acetaminophen. This combination is not recommended in neonates.

Oxycodone dosing at 0.05 to 0.15 mg/kg orally every 4 to 6 hours has been used in neonates, but no data are available to recommend this.

Mixed Opioid Agonist–Antagonists

Nalbuphine is a mixed agonist–antagonist opioid receptor drug; therefore its administration in infants of opioid-addicted mothers may precipitate withdrawal. This agent is equianalgesic with morphine and has an analgesic ceiling effect. Additional studies are needed regarding the safety and efficacy of nalbuphine use in

infants. It is not recommended for use in neonates, although it may be useful during opioid drug withdrawal treatment (Jang et al., 2006).

Long-Term Effects of Neonatal Opioid Exposure

Experimental Animal Studies

Perinatal and neonatal opioid exposure in experimental animals is associated with both short-term and long-term adverse neurologic effects that should make clinicians ask whether the use of such medications with questionable benefits is warranted. Opioid receptor-mediated signaling likely has a role in several aspects of early brain development (Durrmeyer et al., 2010). The developing cerebral circulation is extremely vulnerable to physiologic perturbations and the effects of drugs (Volpe, 1998). Cerebrovascular effects of drug exposure early in development can have lifelong consequences, including increased risk of stroke (Barker, 2000; Hanson et al., 2004; Craft et al., 2006). Data from previous studies suggest that perinatal narcotic exposure restricts brain growth, induces neuronal apoptosis, and alters behavioral pain responses later in life (Kirby et al., 1982; Handelsmann and Dow-Edwards, 1985; Seatriz and Hammer, 1993; Hu et al., 2002). The acute effects of exogenous narcotics, including morphine, on the developing cerebral circulation have been described in piglets and include modulation of prostaglandin-induced pial artery dilation during hypoxia, alteration in endothelin production, and increases in endothelin A receptor messenger ribonucleic acid expression (Armstead et al., 1990; Armstead, 1996; Van Woerkom et al., 2004). Endogenous opioids are important regulators of cerebrovascular tone and angiogenesis (Pasi et al., 1991; Blebea et al., 2000; Gupta et al., 2002; Poonawala et al., 2005). Permanent neurobehavioral and neuropathologic changes are demonstrable in a rodent model of neonatal stress and morphine exposure (McPherson et al., 2007; Boasen et al., 2009; Vien et al., 2009). Understanding the clinical relevance of these animal studies regarding the long-term effects of neonatal opioids is difficult because of species differences in the timing of brain development, the development of opiate receptors and major neurotransmitter systems, and the pharmacokinetics of administered opioids.

Clinical Studies

Clinical studies addressing the short-term and long-term effects of prolonged opiate use in neonates are limited. The few that exist are contradictory and confounded by illness severity. Bergman et al. (1991) described reversible encephalopathic changes in neonates receiving long-term sedative and narcotic infusions. Rože et al. (2008) presented 5-year neurodevelopmental outcomes in very low birth weight infants exposed to prolonged sedation or analgesia (defined as more than 7 days of sedative or opioid drugs). They found that exposed very low birth weight infants more frequently had severe or moderate disability at 5 years (42%) compared with those who were not exposed (26%), but after adjustment for gestational age and propensity score (as a way to ensure that treatment effects are compared only between infants who are equally likely to receive that treatment), the association was no longer significant.

Preterm infants (23 to 32 weeks' gestation at birth) evaluated at 36 weeks' postconceptual age in the NEOPAIN study demonstrated neurobehavioral abnormalities if exposed to morphine (Rao et al., 2007). A small, pilot follow-up of the NEOPAIN trial that included just 19 patients aged from 5 to 7 years showed an association between those given preemptive morphine infusions and smaller

head circumference, lower body weight, increased social problems, and altered response latencies (Ferguson et al., 2012).

A retrospective analysis of 100 extremely low birth weight premature infants found a correlation between worse cognitive scores on the Bayley Scales of Infant Development III test administered at 20 months of age with high levels of opioid exposure in the neonatal period after neonatal and social confounders had been controlled for (Koczek et al., 2016).

A prospective cohort of 188 infants born very preterm (mean 27.4 weeks) admitted to a single NICU were tracked for clinical course, painful procedures, and morphine exposure. When multiple clinical confounders were controlled for, brain MRI performed at term equivalent gestation in these neonates demonstrated a strong statistical association of morphine exposure with smaller cerebellar volumes and poor motor and cognitive outcomes (Zwicker et al., 2016). Possible confounders, including illness acuity, additional medications such as steroids and benzodiazepines, and morphine given preemptively make these results difficult to interpret (van den Anker et al., 2016).

Highlighting the conflicting reports in this area of research, MacGregor et al. (1998) demonstrated no adverse neurodevelopmental outcomes in a small group of newborns who received morphine for a median of 5 days. However, other investigators conducted a 5-year follow-up study on a subset of 60% of 150 neonates in the randomized controlled trial of preemptive analgesia for ventilated preterm neonates conducted by Simons et al. (2003). Their regression analysis, controlling for open-label morphine and clinically relevant variables, implied a trend toward more negative outcomes in individuals who received morphine with respect to intelligence, visual-motor integration, behavior, chronic pain, and health-related quality of life. Morphine use, both preemptive and open label, was also associated with a worse performance on the visual analysis subset of the intelligence quotient (IQ) test (de Graaf et al., 2011). When the same investigators conducted a follow-up at 8 to 9 years of age on a different subset of 80 of the original 150 patients, they obtained different results. Parents were asked to fill out the Dutch version of the Behavior Rating Inventory of Executive Functioning questionnaire, and the children underwent IQ testing. While the results of the IQ testing did not differ between the two groups, the questionnaire results implied that children aged 8 to 9 years who were exposed to morphine had significantly fewer problems on the subscales of inhibition, organization of materials, and monitoring as observed by parents and on the subscale of planning and organization as observed by their teachers (de Graaf et al., 2013). Eighty-nine of the original 150 were also assessed at 8 to 9 years of age for differences in thermal detection and pain thresholds, incidence of chronic pain, or overall neurologic functioning. No differences were found between those who received continuous morphine infusion in the NICU for preemptive analgesia and those who did not (Valkenburg et al., 2015).

The conflicting nature of these studies, multiple clinical confounders, and the fact that none of these studies were adequately powered to address the issue of long-term effects of neonatal morphine exposure make the question of long-term effects of morphine on the developing brain an area in need of robust research.

Topical and Local Anesthetics

Lidocaine reduces the pain and stress of venipuncture and IV catheter placement (Larsson et al., 1998, 1998b; Long et al., 2003). EMLA contains the active ingredients lidocaine and prilocaine.

The cream can be placed on the area where anesthesia is desired and then covered with an occlusive dressing for 1 hour before the procedure. Longer application times provide deeper local anesthetic penetration but can lead to toxicity. There is a slight risk of methemoglobinemia with the use of EMLA cream in patients who are glucose 6-phosphate dehydrogenase deficient and in infants younger than 12 months who are also receiving methemoglobinemia-inducing drugs such as acetaminophen, sulfonamides, nitrates, phenytoin, and class I antiarrhythmics. A rare occurrence, methemoglobinemia can happen when hemoglobin is oxidized by exposure to prilocaine. EMLA cream should not be used in patients with methemoglobinemia (Table 34.1 for recommended maximum doses of EMLA cream by age and weight). A study of 30 preterm infants found that a single 0.5-g dose of EMLA cream applied for 1 hour did not lead to a measurable change in methemoglobin levels (Taddio et al., 1995b). A systematic review concluded that EMLA cream diminishes the pain during circumcision. Limited efficacy was noted with pain from venipuncture, arterial puncture, and percutaneous venous line placement (de Oliveira Marcatto et al., 2011). EMLA cream was not found to diminish pain from heel lancing (Taddio et al., 1998). Oral sucrose or glucose administration may be as effective as EMLA cream for venipuncture (Abad et al., 2001; Gradin et al., 2002).

Sedatives

Benzodiazepines

Benzodiazepines such as lorazepam and midazolam are sedatives that activate γ -aminobutyric acid receptors and should not be used in place of an appropriate pain medication as this class of medication has no analgesic effect. For painful procedures an analgesic must be used in conjunction with the benzodiazepine. Benzodiazepines are administered to decrease irritability and agitation in infants, providing sedation.

In ventilated infants, benzodiazepines can help to avoid hypoxia and hypercarbia from breathing out of synchrony with the ventilator, although the common use of synchronized infant ventilators makes this clinical problem much less likely. When benzodiazepines are given as continuous infusions, dosing often escalates rapidly to maintain apparent sedation, creating a need for prolonged weaning. In three small clinical trials, midazolam provided more sedation to ventilated preterm neonates than placebo on the basis of sedation scales that had not been validated for preterm neonates. In the NOPAIN trial, midazolam was associated with a statistically significant higher incidence of adverse neurologic events such as death, severe intraventricular hemorrhage, and periventricular leukomalacia

(Anand et al., 1999). A metaanalysis concluded that there are “insufficient data to promote the use of intravenous midazolam infusion as a sedative for neonates undergoing intensive care ... [and there are] concerns about the safety of midazolam in neonates” (Ng et al., 2012).

Use of such medications has been associated with abnormal neurologic movements in both preterm infants (Lee et al., 1994) and term infants (Chess and D’Angio, 1998). In rats, prenatal exposure to diazepam results in long-term functional deficits and atypical behaviors (Kellogg et al., 1985); exposure of 7-day-old mice to diazepam induces widespread cortical and subcortical apoptosis (Bittigau et al., 2002); and midazolam potentiates pain behavior, sensitizes cutaneous reflexes, and has no sedative effect in newborn rats (Koch et al., 2008). Prolonged midazolam dosing in preterm infants has been correlated with abnormal hippocampal growth and poorer neurodevelopmental outcomes (Duerden et al., 2016). Whether these data can be extrapolated to human infants is unknown, but clinicians have reason to be concerned and should use these drugs with caution in the NICU.

Dexmedetomidine

Dexmedetomidine is a potent and relatively selective α_2 -adrenergic receptor agonist indicated for the short-term sedation of patients in intensive care settings, especially those receiving mechanical ventilatory support. The drug is administered by either bolus doses for short procedural sedation (1 to 3 $\mu\text{g/kg}$) or continuous IV infusion (0.25 to 0.6 $\mu\text{g/kg}$ per hour). Because dexmedetomidine does not produce significant respiratory depression, it has been used for procedural interventions in spontaneously breathing infants (Barton et al., 2008; Chrysostomou et al., 2009). As neonatologists have become more familiar with dexmedetomidine, its use has increased (O’Mara et al., 2009; Su and Hammer, 2011; O’Mara et al., 2012; Estkowski et al., 2015; McAdams et al., 2015; Plambech and Afshari, 2015); however, short-term and long-term safety and effectiveness information in neonates is limited. Animal studies have been reassuring, including several demonstrating that dexmedetomidine may be neuroprotective (Duerden et al., 2014; McAdams et al., 2015; Ren et al., 2016).

Nonpharmacologic Analgesia

Nonpharmacologic interventions for prevention or relief of neonatal pain and stress are numerous and widely publicized in the medical literature. These interventions have been used either as the sole method of pain control or in combination with pharmacologic interventions. Because opioid analgesia and sedation have not been proved to be efficacious and may possibly be harmful, alternative methods of pain and stress relief have been evaluated for efficacy and safety. A variety of approaches have been investigated. As stated clearly by Golianu et al. (2007), “these therapies may optimize the homeostatic mechanisms of the infant, thereby mitigating some of the adverse consequences of untreated pain, as well as facilitating healthy physiologic adaptations to stress.” However, widespread adoption of specific techniques is not consistent.

Orally administered sucrose is the most widely studied non-pharmacologic analgesic; it safely and effectively reduces the acute behavioral response to procedural pain (Stevens et al., 2013). Sucrose does not, however, reduce spinal reflex responses, cortical activity (Slater et al., 2010), or hyperalgesia (Taddio et al., 2009), raising philosophical and ethical questions about the use of sucrose for procedural analgesia. “Sugar may be better understood not as an analgesic, removing or relieving pain, but as a compensating

TABLE 34.1 EMLA Cream: Recommended Maximum Dose by Age and Weight

| Age and Body Weight Requirements | Maximum Total EMLA Dose (g) | Maximum Application Area (cm^2) | Maximum Application Time (h) |
|----------------------------------|-----------------------------|--|------------------------------|
| Birth to 3 months or <5 kg | 1 | 10 | 1 |
| 3 to 12 months and >5 kg | 2 | 20 | 4 |

Data from Taketomo CK, Hodding JH, Kraus DM, editors. *Pediatric & Neonatal Dosage Handbook*, 2014–2015. 21st ed. Hudson: Lexi-Comp; 1246–1248.

pleasure” (Wilkinson et al., 2012). Sucrose use in extremely preterm, unstable, and/or ventilated neonates is not adequately addressed in the literature nor is the effect of repeated sucrose administration (Stevens et al., 2013). When combined with other nonpharmacologic analgesic interventions, sucrose continues to effectively decrease neonatal behavioral responses to pain. Sucrose plus nonnutritive sucking, for example, provides improved pain relief (as assessed by behavioral scores) from heel lance when compared with placebo or either method alone (Thakkar et al., 2015).

Nonnutritive sucking with pacifiers reduces pain responses to heel prick, injections, venipuncture, and circumcision procedures (Shiao et al., 1997; South et al., 2005; Sexton and Natale, 2009). Infant massage has been demonstrated to decrease plasma cortisol and catecholamine levels in preterm infants (Kuhn et al., 1991; Acolet et al., 1993). Preterm neonates benefit from skin-to-skin contact (Ludington-Hoe, 2015) or facilitated tucking (Liaw et al., 2012; Lopez et al., 2015) to ameliorate acute procedural pain responses.

Skin-to-skin contact (also termed *kangaroo care*) is associated with greater physiologic stability and reduced responses to acute pain (Ludington-Hoe and Swinth, 1996; Fohe et al., 2000; Gray et al., 2000; Johnston et al., 2003; Bergman et al., 2004; Ludington-Hoe, 2015). Kangaroo care can decrease Neonatal Infant Pain Scale scores after vitamin K injections (Kashaninia et al., 2008). Maternal rocking has been shown to diminish neonatal distress (Jahromi et al., 2004). Breastfeeding during kangaroo care reduces the physiologic and behavioral responses to acute pain and stress

in neonates and has been recommended as the first line of treatment (Shah et al., 2006; Osinaike et al., 2007; Obeidar and Shuriquie, 2015), as does feeding of expressed breast milk (Sahoo et al., 2013).

The Neonatal Individualized Developmental Care and Assessment Program (NIDCAP) systematically changes a protocol-based model of nursing care to a relationship-based approach (Als et al., 1994). There is a significant body of empiric evidence that use of the NIDCAP approach improves the clinical and neurodevelopmental outcomes of preterm infants (Als et al., 1994; Als and Gilkerson, 1997; Brown and Heermann, 1997; Westrup et al., 2000; Kleberg et al., 2002; Wielenga et al., 2007), but metaanalyses of published studies could not demonstrate any improvement in long-term outcomes (Jacobs et al., 2002; Symington and Pinelli, 2006).

Another approach is multisensory stimulation (sensorial saturation) of preterm infants undergoing painful procedures. This approach entails simultaneous gentle massage, soothing vocalizations, eye contact, smelling a perfume, and sucking on a pacifier. This technique was associated with analgesia and calming of the infants in several reports from one unit (Bellieni et al., 2001, 2002, 2007, 2012).

Music therapy may reduce the behavioral and physiologic responses to acute procedural pain (Hartling et al., 2009). Warmth is also an analgesic for acute procedural pain in healthy term infants (Gray et al., 2012, 2015). Other interventions such as white noise (Karakoc and Turker, 2014) and flaxseed pillows (Diesel and Ercole, 2012) are under investigation for their effects as either an acute analgesic or a modulator of chronic pain.

Summary

Recognition and treatment of pain and discomfort in the neonate remain challenging issues. Despite significant progress in the understanding of human neurodevelopment, pharmacology, and more careful attention to the care of sick infants, there is still much to learn. While protecting and comforting these patients are important goals, available evidence remains limited, and yet external regulatory forces have required intervention to minimize distress. What is known about adult or older pediatric patients has frequently been applied to infants. Some good has come from these endeavors, but errors have been made along the way.

It is important to minimize pain and distress in these patients to avoid more aggressive interventions. Techniques such as grouping interventions and examinations with nursing care times and limiting skin breaking procedures by batching or decreasing blood draws can go a long way toward preventing unnecessary pain. Bedside providers should feel empowered to advocate for their patients by

making time for appropriate and effective pharmacologic and nonpharmacologic analgesia as a key step in pain prevention (Stevens et al., 2011). Such care will minimize the risks of adverse effects on neurodevelopment. Learning to provide good care without doing harm should be the goal.

Nonpharmacologic methods of pain and distress control should be explored further. When pharmacologic intervention is necessary for pain control, use the least amount of drug that controls the pain. Escalation of drug doses may, in fact, compound the problem.

As newer techniques (such as NIRS and amplitude-integrated electroencephalography) and medications (such as dexmedetomidine) are introduced to clinical practice, it must be demonstrated that such additions achieve the goal of pain control and are safe over the lives of our patients. Better tools are needed to help optimize the outcomes for our fragile infants.

Palliative Care

DONNAMARIA E. CORTEZZO AND BRIAN S. CARTER

KEY POINTS

- Palliative care is the total care of a patient with a life-limiting illness regardless of the disease trajectory or treatment options chosen.
- There is a special focus on pain/symptom management, communication, quality of life, family support, and grief support.
- Roughly one-third of deaths in children's hospitals in the United States occur in neonatal intensive care units (NICUs). Many babies and families in the NICU would benefit from palliative care.
- While palliative care is essential to individuals in the NICU, it is often overlooked, and there are still many barriers to its being considered or implemented in suitable cases.
- Palliative care can readily be integrated into the management of neonates with life-limiting illnesses and can be provided concurrently with cure-oriented or life-extending care.

What Is Palliative Care?

The concept of palliative care has been acknowledged in medicine for centuries. The name is derived from the Latin word *palliare*, meaning to cloak, and has been more broadly interpreted to mean “to alleviate without the intent of curing.” Over the years the definition and scope of palliative care have evolved (Lutz, 2011). The field gained great momentum in the adult world during the 1960s with the hospice movement and the realization that modern medicine alone does not address all of the issues patients with serious and life-limiting illnesses experience. More recently, the incorporation of palliative care into the pediatric world has become critical (Feudtner et al., 2003; Knapp et al., 2009; Wolff et al., 2010; Bona et al., 2011; Jones, 2011; Rendón-Macías et al., 2011; Wolfe, 2011; Wolfe et al., 2011; Feudtner et al., 2013; Catlin et al., 2015). The World Health Organization defines pediatric palliative care as the total care of a child with a life-limiting illness. It involves caring for the mind, body, and spirit of the child and supporting the family through the process. It begins with diagnoses and continues regardless of the disease trajectory or treatment options chosen. There is a special focus on pain and symptom management and alleviating distress through a multidisciplinary approach (World Health Organization, 2015). Palliative care is not limited to EOL care. It can occur concurrently with other

treatments in an attempt to cure a patient or prolong his or her life independently of when the transition to EOL care occurs. Hospice care is a small but important part of palliative care. Once it has been determined that there is no chance of meaningful survival, the focus of the care shifts to pain and symptom management, grief support, preparing for the dying process, and bereavement support (Davis et al., 2015).

In recent years, the American Academy of Pediatrics has acknowledged the importance of this growing field and recognizes that all large healthcare organizations providing care to children with life-limiting illnesses should have a dedicated pediatric palliative care team. The American Academy of Pediatrics has discussed in detail the principles for palliative care as well as the importance of educating trainees (American Academy of Pediatrics, Committee on Bioethics and Committee on Hospital Care, 2000; Section on Hospice and Palliative Medicine and Committee on Hospital Care, 2013). Governing academies and families alike have come to see the importance of the provision of palliative care in pediatrics and more specifically in taking care of the sickest babies. The US News and World Reports Best Children's Hospitals Rankings in Neonatology now include a section for neonatal intensive care unit (NICU)-specific palliative care programs.

Despite the recent increasing focus on neonatal palliative care, the idea has been around for decades. In the 1970s the difficulties of withholding therapies in a special care nursery were described for the first time (Duff and Campbell, 1973). In this landmark article, the authors describe a collaborative process in which parents and physicians through joint decision making determined the likelihood of a meaningful life as an outcome from the special care nursery was very low for 43 babies and opted to redirect care for them. They also acknowledge the difficulty of these decisions for parents and physicians, something that is still faced today. Several years later, the notion of adapting concepts from an adult hospice model to address the issues of caring for a neonate dying in various settings was described (Silverman, 1982; Whitfield et al., 1982; Butler, 1986; Landon-Malone et al., 1987).

Paradigms of Palliative Care

There are multiple paradigms in which palliative care can be provided (Fig. 35.1). In Fig. 35.1 the first model represents the serial approach. This is the earliest view of palliative care. Once a terminal

• **Fig. 35.1** Various models for providing palliative care. (Modified from Milstein J. A paradigm of integrative care: healing with curing throughout life, “being with” and “doing to.” *J Perinatol.* 2005;25:563–568.)

condition has been diagnosed, curative therapies continue until they are seen as futile. Then palliation and comfort measures are offered until the point of death. After death, bereavement support is offered. As the field of palliative care has evolved, the adult world has adapted the parallel model in which palliative care is introduced early in combination with curative therapies, and as the disease trajectory changes with time, the care model changes with it. Again, once death occurs, bereavement support is offered. The final model, the integrated model, is one that has been adopted most often by the growing field of pediatric palliative care and is most conducive to the unique environment of the NICU. When a life-limiting diagnosis is made, the concepts of palliation are introduced along with curative therapies and change with the disease trajectory. With recognition that the family is experiencing loss on multiple levels at the time of diagnosis, bereavement and grief support are offered in a multidisciplinary fashion from the time of diagnosis, through the entire illness course, and after death (Milstein, 2005).

Because the perinatal/neonatal period is so unique, it requires an approach to palliative care different from that in most other fields. The perinatal/neonatal period is usually a time of joy, anticipation of life, and hope for many memories to be made by growing as a family. When there is a diagnosis of a life-limiting condition that results in a fetal or neonatal death, every milestone and stage of the pregnancy, birth, life, and death are very different from what was hoped for and anticipated (Carter, 2004; Carter et al., 2006; Breeze et al., 2007; Munson and Leuthner, 2007; Romesberg, 2007; Balaguer et al., 2012; Catlin et al., 2015). Similarly, in the NICU environment, providers are trained to offer intensive and invasive therapies with the goal of saving lives. It

can be challenging to shift goals of care in the face of a life-limiting illness (Carter et al., 2006; Kain, 2006; Wright et al., 2011; Cortezzo et al., 2013).

Scope of the Problem

While neonatal–perinatal palliative care provides unique challenges for families and healthcare providers alike, it is something that most individuals who provide care for neonates will be faced with. Despite the many advances in medical therapies and improvements in neonatal survival and outcomes, newborns will still die. Often these babies will die regardless of the treatment options chosen by the family and medical care team. In 2013 in the United States, there were more than 1 million fetal deaths, with more than 20,000 occurring after 20 weeks’ gestational age. In addition, there were more than 15,000 neonatal deaths, accounting for nearly 70% of deaths within the first year of life (MacDorman and Gregory, 2015). Most of those who died within the first year experienced severe and chronic illnesses stemming from the time of birth. Roughly one-third of deaths in children’s hospitals in the United States occur in the NICU setting (Brandon et al., 2007). As a result, most medical care providers who care for neonates will be faced with the death of a patient and navigating the goals of care with a family.

Given the likelihood that neonatologists will be faced throughout their careers with patients having life-limiting illnesses, it is pertinent that they incorporate palliative care into daily practices to best care for patients and families. The uncertainty of prognosis, physical constraints of the NICU, time constraints, moral distress, and lack of education are known barriers to providing palliative care in the NICU (Lantos et al., 1994; McHaffie et al., 1999; Romesberg, 2007; Davies et al., 2008; Wright et al., 2011; Cortezzo et al., 2013). In an intensive care setting it can be challenging to shift from cure-directed aggressive and invasive interventions to palliation and comfort care. However, early initiation of palliative care has been associated with improved memory making, decreased pain, decreased rates of invasive procedures that will likely not change the outcome, and increased parental satisfaction (Eden and Callister 2010; Wolff et al., 2010; Cortezzo et al., 2015; Kenner et al., 2015). Consequently, it is imperative that healthcare providers view success for the unique subset of patients with life-limiting illnesses who will die despite intensive medical interventions as eliminating unnecessary suffering, supporting families through the dying process, and helping them find meaning in their baby’s life (Milstein, 2005; Carter et al., 2011). Failure in these situations is not the inability to sustain life but rather unnecessary pain and suffering and an undignified death.

Which Patients Benefit From Palliative Care in the Neonatal Intensive Care Unit?

Many neonates will respond to intensive care therapies, graduate from the NICU, and lead meaningful lives. Knowing this, which patients and families would benefit from palliative care in the NICU setting? There is a role for palliative care in caring for neonates with serious but possibly treatable conditions. Arguably, many aspects of palliative care should be incorporated into the multidisciplinary approach to the care of any baby in the NICU. Any family member of a newborn requiring resuscitation or intensive interventions, regardless of the ultimate outcome, experiences grief and loss. The family has to alter its expectations for a healthy and

uneventful pregnancy leading to a healthy baby. The family often requires spiritual, emotional, and psychosocial support to deal with this trauma both in the immediate period and moving forward (Sydor-Greenberg and Dokken, 2000).

However, there is a special and more pronounced role for palliative care when the likelihood of long-term survival is minimal. Often, when death is almost certain, continuing life-sustaining treatments may only prolong the suffering of the neonate and give the family false hope of meaningful survival. The care initiated and the treatments that follow may be aggressive and at the expense of the comfort of the baby. Palliative care focuses on the prevention and relief of physical pain and suffering of the periviable extremely premature infant, actively dying infants, or those severely compromised and possibly technology dependent, as well as on supporting the needs of the family (Lorenz, 2004). Everyone involved in the care of these neonates, as well as the neonates themselves, can strongly benefit from this type of care. Regardless of whether or not a neonate dies, lives with a permanent impairment, or goes on to live a normal life, there is a necessary role for palliative care. Beyond addressing symptoms such as pain, this approach offers support to families and addresses short-term and long-term measures to ensure that the infant has the best quality of life for as long as he or she may live (Carter and Levetown, 2004; Carter et al., 2011).

While every patient and family dynamic is different and goals need to be explored for each patient, there are several categories where it is appropriate to discuss transitioning from life-extending therapies to comfort measures (Carter and Bhatia, 2001; Carter, 2004; Carter and Levetown, 2004; Carter et al., 2006; Romesberg, 2007; Carter et al., 2011):

1. Any periviable, extremely premature newborns based on gestational age or birth weight, especially when they have significant complications
2. Neonates with multiple congenital anomalies incompatible with long-term survival. Under these circumstances, intensive care therapies may alter the time course and the baby's/family's life experience but will not, unfortunately, change the long-term outcome. These conditions may involve any single-organ or multiple-organ system and at times are the result of genetic abnormalities.
3. Newborns who have received intensive interventions and despite efforts are not responding to therapy, continue to decline, or have continued life-threatening events (severe hypoxic-ischemic encephalopathy, multiple-organ system failure, overwhelming sepsis, necrotizing enterocolitis totalis).

When these unfortunate situations arise, it is important to have a multidisciplinary approach to caring for the patient and family. The NICU provides a unique environment in which intensive life-sustaining therapies are provided that focus on comfort of the patient and involvement of the family in the care process (Carter, 2004). It is one of the few places in hospitals where a multidisciplinary team (physicians, nurses, social workers, chaplains, etc.) is focusing on multiple aspects of the total care of the baby-family unit. This lends itself nicely to the provision of palliative care because much of the framework already exists. Yet, while many care providers in NICU settings feel they are comfortable and competent in providing EOL care for neonates, there is a wide variety in the care patients receive and in the discussions of care with families (Leuthner, 2001; Carter, 2004; Cortezzo et al., 2015). Similarly, there may be attitudinal barriers to consulting palliative care clinicians. Evidence suggests, however, that once the need for and importance of palliative care in the NICU are realized, palliative

care clinicians can facilitate it being readily integrated into the management of neonates with life-limiting illnesses (Kang et al., 2014).

Components of Palliative Care in the Neonatal Intensive Care Unit

The major components of palliative care incorporated into the care of neonatal patients with a life-limiting illness are a focus on communication, quality of life, family support, and grief support (Catlin and Carter, 2002; Madden et al., 2015). Ideally, care providers who have become familiar with the family (including neonatologists, nurses, social workers, and chaplains) and have developed a rapport with them should initiate and be present for difficult conversations. These conversations with family members should be clear, direct, and honest (Janvier et al., 2014). They should happen in a quiet environment where the family has the care provider's undivided attention. Parents wish that difficult news be delivered in an honest and compassionate manner that lets them know their child matters (Widger and Picot, 2008; Kavanaugh et al., 2009; Armentrout and Cates, 2011; Janvier et al., 2014). After the diagnosis and the relative certainty of the prognosis have been discussed, the focus of these conversations should shift to exploring the values of the family, wherein the care team can better understand the family, how the family members make decisions, and what is important to them.

Key among goals in these conversations is helping to identify—and often redefine or redirect—their hopes. By being open and compassionate, providers can give family members a sense of realistic hope during this difficult time without misleading them toward a false sense of the likely survival (Widger and Picot, 2008; Eden and Callister, 2010; Armentrout and Cates, 2011). It is often helpful to focus the conversation on what is meaningful to the family members in the context of a poor prognosis (Carter et al., 2011). Their idea, or object, of hope may change over the course of the baby's life. With a better understanding of the family's values, the care team can participate with the family in shared decision making and ultimately define or redefine the goals of care. These conversations and the decisions made are unique to each family regardless of the diagnosis. It is not uncommon for parents and the care team to have different agendas and priorities during this time (Midson and Carter, 2010). It is critical to attend to the parent's priorities and ensure that they feel valued, listened to, and a member of the care team. It is the care provider's job to understand the family's values and goals and to make medical recommendations based on those goals. There are times when the choices of the family may be in opposition to the views of the care team (Kopelman, 2006; Back, 2009). It is the care team's obligation to continue conversations with the intent of better understanding the reasoning behind the family member's decisions/goals and supporting them through the process. The goal should not be to try to convince the family that an alternative approach is most appropriate. In partnership with the NICU team, palliative care clinicians may be instrumental in facilitating such ongoing conversations, especially as primary neonatal clinicians may change every week or every 2 weeks.

When the end of life (EOL) is approaching, it may also be important to have open conversations about organ or tissue donation, autopsy, and funeral, memorial, or burial services. Many NICUs have a team of social workers, chaplains, and psychologists to help attend to these needs. The addition of palliative care

clinicians can bring expertise in providing additional support during these very unique and difficult times. When there is an anticipated compassionate withdrawal of life-sustaining medical treatment, it may be beneficial to contact a liaison with a regional organ procurement organization to engage families in discussions about organ/tissue donation.

Regardless of the family's care goals or treatment options, the baby's quality of life should remain paramount. Care should be taken to ensure that painful procedures are minimized, unnecessary tests stopped, the physical environment is made comfortable and conducive to family bonding, and that pain and symptoms are addressed with nonpharmacologic and pharmacologic management when necessary.

Grief and Bereavement Support

Grief support should be initiated shortly after a life-limiting diagnosis. Initially such support may focus on grieving the loss of the healthy newborn and the life the family members anticipated in the context of still celebrating and enjoying their baby. Attention should be given to ensure the parents, siblings, grandparents, and extended family members are able to make memories with the baby. During this stressful time, especially if it is their first child, parents are often unable to think about what memories would be important for them to make. Some families wish to take pictures, have handprints/footprints or molds made, record heartbeats, bathe the child, sing/read to the child, take the child outside, have the child meet a family pet, taste foods, sleep in a bed, or participate in spiritual/religious ceremonies. Every effort should be made to help these families maximize the experiences they have with their baby during what may be a brief life span. Bereavement support for parents, siblings, and family members should start before the death of the baby and continue for a period afterward (Kenner et al., 2015). Parents appreciate bereavement support and follow-up phone calls from or meetings with physicians who provided care for their child and other forms of acknowledgment such as condolence cards (Kenner et al., 2015). It is also imperative to recognize that staff members benefit greatly from grief support (Cavaliere et al., 2010; Cortezzo et al., 2015). Often the NICU staff has been involved in the care of the baby for much of his or her life and has spent time becoming familiar with the family. News of a poor prognosis can be emotionally trying for such staff as well. Because the staff are attending to the immediate care needs of the baby, family, and other babies in the unit, they may be unable to process such difficult news. It is important that we support them as well.

Timing of the News

Early Prenatal Diagnosis

Families may learn of a life-limiting condition in the early prenatal period, late prenatal period, or early neonatal period (Wolfe et al., 2011). While the job of the healthcare team remains the same in supporting the family members and helping them find meaning in their baby's life, the timing can slightly alter the approach to care. If the news is given in the early prenatal period, parents often have time to begin grieving the loss of a healthy pregnancy and reframe their idea of hope. If palliative care is initiated early on, the family members may benefit from the involvement of palliative care providers who learn about the family and support them through the process. They can facilitate bonding and memory making

throughout the pregnancy. They also have time to navigate the goals of care and develop a care plan that includes a birth plan and advance care planning known by all providers at the time of delivery. Box 35.1 highlights important components of a perinatal palliative care birth plan. A delivery room resuscitation plan should be discussed ahead of time with the family (Catlin and Carter, 2002; Widger and Picot, 2008; Balaguer et al., 2012; Engelder et al., 2012; Kenner et al., 2015). But the staff still needs to remain ready to adapt such plans to the reality of the newborn's condition at birth. Families may change their minds, the newborn's condition may be better or worse than anticipated, and decision making remains rather fluid. Ethics and palliative care support may aid parents and facilitate their navigation through difficult decisions and how they choose to spend whatever amount of time they have with their baby.

Late Prenatal Diagnosis

If the news of a life-limiting illness is discovered late in the pregnancy or just before delivery, it often results in a more chaotic and less formulated approach. Teams are working rapidly to provide immediate care to the mother and fetus/neonate. There is often not time to have lengthy discussions or learn the parent's values. In the chaos, communication can be rushed and fragmented. It remains imperative to provide accurate information and support to the parents while making the environment as calm and private as possible, allowing the family members to express their emotions. In the time that follows, discussions can be continued.

Postnatal Diagnosis

If the news of a life-limited illness is not discovered until after delivery, parents are often shocked. Most assume that if a delivery

•BOX 35.1 Components of a Perinatal Palliative Birth Plan

Clarify Maternal Goals

- Site of delivery
 - Community or tertiary
- Fetal monitoring
 - E-FHR, auscultation, none
- Mode of delivery
 - Burdens, benefits, values
- Who will be in attendance?
 - Who matters?
- Maternal and neonatal medications
 - Anesthesia and otherwise

Clarify Neonatal Goals

- Specified components of resuscitation and care
 - Intubate, CPAP, O₂?
 - Medications and lines?
- Site of care of the baby
 - L & D, nursery, ICN, home
- Feeding plan
 - Breast, tube(s), cup, finger, no?
- Special events and spiritual care
 - Memories, mementoes, rituals
- Contingency postdischarge plan

CPAP, Continuous positive airway pressure; E-FHR, external fetal heart rate; ICN, Intensive Care Neonatal; L & D, labor and delivery.

goes well, their baby will be healthy. For them it is an abrupt loss of the healthy baby they were holding moments before they received the news. It is vital to continue to promote bonding with the baby and ease suffering. The care team should use the medical information along with the knowledge of the family's values to shape the goals of care and aid in decision making. Extra time is often necessary in this situation, with care to provide support for the family and staff in redefining and redirecting hope and the goals for the newborn's care.

Parents note that the delivery of the news and the discussions that follow shape their experience with the care team, their memories of time with their child, and their subsequent bereavement. Some parents report that the news about a diagnosis, prognosis, or treatment options were given in an insensitive manner. They wish to be included in the decision-making process and know that their input as parents is what matters the most. They also desire privacy, support, and time to come to terms with their loss (Contro et al., 2002; Davies and Connaughty, 2002; Berg, 2006; Dokken, 2006; Brosig et al., 2007; Henley and Schott, 2008; Eden and Callister, 2010; Armentrout and Cates, 2011).

End-of-Life Care

Palliative care is extremely important during EOL care, when a neonate is imminently dying. Every effort is made to ensure the family members can shape the experience of the death in a way that is most meaningful to them and that they are as prepared as they can be for the dying process. For some families, it is important that they understand the physiologic changes that they will likely see ahead of time. If family members wish to stay in the hospital for the death of their baby, every effort should be made to bring them to a private room within the NICU or to a different location within the hospital. The environment should be as peaceful and homelike as possible. Monitors and unnecessary equipment should be removed. Families should determine who they wish to have

present and if they would like to hold their baby or perform any rituals. Care should be taken to respect any cultural or spiritual desires of the family. If parents desire to take their baby home for EOL care, care providers should coordinate with local home hospice programs or home-health services to ensure that the family will have access to the care, support, equipment, and medication that will be needed during this time. Parents should be reassured that regardless of location, they will not be abandoned and that care will be taken to attend to pain and symptom management. The focus should be on what the team can do for the baby and family as opposed to what the team can no longer do (Catlin and Carter, 2002; Leuthner, 2004; Gale and Brooks, 2006). Symptom management is available with an array of medications (Carter and Jones, 2013), and dyspnea, pain, and agitation should be anticipated and appropriately assessed. Neonates feel pain and other symptoms of distress, and they should be addressed accordingly (Anand and International Evidence-Based Group for Neonatal Pain, 2001; American Academy of Pediatrics et al., 2007). Symptoms that may need to be treated at the EOL include pain, agitation, dyspnea, and secretions (Komatz and Carter, 2015). Nonpharmacologic interventions to address these issues are equally important, such as decreasing stimulation, a soothing environment, massage, elevating the head, fluid restriction, and gentle suctioning. At times, especially during the EOL, nonpharmacologic interventions will not be enough. It is important to anticipate this and alleviate the stress of the family. It is both clinically and ethically appropriate to provide pharmacologic symptom relief. While there may be a concern of hastening death with certain medications (e.g., opioids), at appropriate doses this generally does not happen. The intent to provide relief of pain and suffering, it can be argued, outweighs the small chance of respiratory depression. Tables 35.1–35.2 provide a guide to common pharmacologic symptom management at the EOL. It is important to note that these doses and the medication choices may need to be altered on the basis of the patient's previous exposure.

TABLE 35.1 Symptom Management for End-of-Life Care: Pharmacologic

| Symptom | Medication | Category | Starting Dose (per Kilogram) | Route and Interval |
|------------|----------------|--------------------------|--------------------------------------|------------------------------|
| Pain | Acetaminophen | Antipyretic Analgesic | 15 mg 6–8 mg | PO/PR q6 hour IV q8 hour |
| | Fentanyl | Opioid | 0.5–2 µg | IN/IV q2 |
| | Methadone | Opioid | 0.05–0.2 mg | IV/PO q12–24 |
| | Morphine | Opioid | 0.05–0.2 mg 0.2–0.5 mg | IV/IM q2 PO/sublingual q4 |
| Agitation | Lorazepam | Benzodiazepine | 0.05–0.1 mg | IV q4–6 |
| | Midazolam | Benzodiazepine | 0.05–0.1 mg 0.2–0.3 mg 0.25 mg | IV q2–4 Sublingual IN |
| Dyspnea | Morphine | Opioid | 0.15 mg 0.05–0.1 mg | PO/sublingual q2 IV q2 |
| | Lorazepam | Benzodiazepine | 0.05–0.1 mg | PO/IV q4 |
| Secretions | Atropine | Anticholinergic | 0.01–0.02 mg | PO q2 |
| | Glycopyrrolate | Anticholinergic | 0.01–0.02 mg | IV q4 |
| | | | 0.04–0.1 mg | PO q4 |

IV, Intravenous; IM, intramuscular; IV, intravenous; PO, per os; PR, per rectum; q2, every 2 hours; q2–4, every 2–4 hours; q4–6, every 4–6 hours; q6, every 6 hours; q8, every 8 hours; q12–24, every 12–24 hours.

TABLE 35.2 Symptom Management for End-of-Life Care: Nonpharmacologic

| Symptom | Action | Provider |
|-------------------|---|---------------------|
| Pain or agitation | Reduce ambient noise | Clinician |
| | Reduce procedural touching (handling, suctioning, laboratory tests, and imaging) | Clinician |
| | Reduce temperature swings | Clinician |
| | Swaddle; facilitated tuck | Clinician or parent |
| | Nonnutritive suckling | Clinician or parent |
| | Skin-to-skin contact | Parent |
| Dyspnea | Postural positioning (may be lateral, upright, or prone; may include neck, chest, or shoulder roll) | Clinician or parent |
| | Consider fan or humidified air | Clinician |
| Secretions | Oral and nasal suctioning | Clinician or parent |

Ethical Concerns

With advances in equipment and medicine, and more rigorously studied and implemented practices, increasingly neonates are benefiting from their stays in the NICU. The age of viability has dropped with continuously improving clinical capabilities (Rennie, 1996; MacDonald, 2002). As we become better at saving one group, the limits are pushed for another group of neonates (Singh, 2004). Yet with these advances, have come a variety of uncertainties and outcomes. Difficulty remains around the borderlines of viability with resuscitation, and when to forego life-sustaining therapies, or whether to redirect care. At 22 weeks of gestation some centers universally offer a treatment trial of intensive care whereas others do not, or do so on only an individual basis (Patel, Kandefer, et al., 2015; Rysavy, Li et al., 2015).

It is often difficult to predict a neonate's course or future complications. This uncertainty brings many questions and discussions among professionals and families about the neonate's response to intensive care, complications encountered, and what actions are in neonate's best interests (Whitelaw, 1986; Rhoden, 1989; Silverman, 1992; Sanders, Donohue et al., 1995; Rennie, 1996; MacDonald, 2002; Lorenz, 2004; Silverman, 2004). Families are often faced with decisions that are not seen elsewhere in medicine, and these decisions are complicated by both the urgency of need for action and the uncertainty of prognosis (Wolfe, Hinds et al., 2011). Many times both families and care teams feel that once care is initiated, everything possible must be done to save the neonate. However, there may come a point in time when certain life-sustaining interventions are considered acceptable by some families whereas others believe such continued intervention or technology dependence render a quality of life for their baby that they do not find acceptable.

Both ethically and legally withholding an intervention or withdrawing one already started are considered equivalent (Bell and Newborn, 2007). In other fields of medicine this seems to be more readily accepted. The thought of withdrawing LSMT from a neonate leads many parents to believe they are actively aiding in their baby's death. When based on notions or descriptions of futility or a perceived quality of life, a contest of whose perception of these terms matters most (clinicians or families) often results. Consequently, physicians may have difficulties addressing these issues, discussions may be limited, and if they occur it is late in

the treatment course (Lantos, Tyson et al., 1994; McHaffie, Cuttini et al., 1999).

Withdrawing/withholding LSMT, while a relatively infrequent phenomenon in a given NICU, is the most frequent mode of dying in both neonatal and pediatric ICUs (Walther, 2005; Fontana, Farrell et al., 2013; Meert, Keele et al., 2015). It is understandable that parents want to be sure that there is essentially no chance of survival before such decisions are made and it warrants open communication, transparency in prognostication, and attention to empathy (Singh 2004, Meyer, Brodsky et al., 2011).

Barriers to Palliative Care in the Neonatal Intensive Care Unit

While palliative care is essential to individuals in the NICU, it is often overlooked and there are many barriers. The NICU environment is often noisy and crowded, with little room for privacy (Carter and Bhatia, 2001). Also, with current advances in technology, death may be viewed as a failure as the technologic imperative is so operant that if a therapy is available, it must be used without full consideration of how burdensome it is or if it will ultimately benefit the neonate (Carter and Bhatia, 2001; Carter and Miller-Smith, 2016). Often families are overwhelmed by the technology and feel an incredible burden that the decisions are solely on their shoulders. If the outcome is certain and the treatment is a standard of care, then this is often not an issue. However, there is rarely such certainty.

Training in Neonatal–Perinatal Palliative Care

Clinicians' discomfort to address the limits of medicine and technology and redirect the prevailing care paradigm from one that is disease based and cure oriented to one that is palliative and comfort oriented is likely contributed to by a relative lack of palliative care training in neonatal and perinatal training programs. A study was published regarding training of neonatal fellows in discussions with families and helping them make decisions regarding critically ill neonates (Boss et al., 2009). Fellows from 83% of the accredited programs participated. For the most part, all of the fellows felt confident in their medical training. However, more than 40% stated that they had not had any formal communication training or clinical communication skills training. More than 90% felt that training in this area—specifically palliative care, spiritual needs, and managing conflicts of opinion—was lacking or nonexistent in their training program. It is imperative that neonatologists learn these skills because families who have lost a child often cite how important it is that the physician communicates with them in a way they can understand/handle and address all of their palliative care and spiritual needs so that collaboratively they can come up with a clear plan (Baker et al., 2007; Boss et al., 2009; Michelson et al., 2009; Orgel et al., 2010; Cortezzo et al., 2013, 2015).

Research Opportunities/Future Directions

While there have been many advances in the field of neonatal palliative care in recent years, there are still many exciting opportunities for research. Studies have yet to determine which interventions offer optimal pain and symptom management at the EOL. There are also many opportunities for research addressing communication

training and quality improvement investigations looking at the timing and delivery of palliative care, which paradigm of delivery is most effective, and how it will alter the course of living with neonatal loss for these families.

Immunology of the Fetus and Newborn

JOERN-HENDRIK WEITKAMP, DAVID B. LEWIS, AND OFER LEVY

KEY POINTS

- The fetus and newborn express a distinct and evolving immune system that mediates transition from intrauterine life to the microbe- and antigen-rich world.
- Multiple mechanisms including regulatory T cells help ensure maternofetal immune compatibility.
- Newborns are highly reliant on soluble and cellular innate immune mechanisms whose ontogeny depends on gestational and postnatal age.
- Adaptive immunity in newborns features distinct ontogeny and functionality of T and B cells.
- Primary immunodeficiencies that present in early life include genetic defects in innate and adaptive immunity.
- Maternal and early-life immunization are the most effective biomedical interventions to prevent infection in the newborn and young infant.
- Some live vaccines such as bacille Calmette–Guérin, which is given to newborns in tuberculosis-endemic regions, may afford broad protection against infections with antigenically unrelated pathogens.

Of any age group, newborns and young infants are at the highest risk of infection-induced morbidity and death. Understanding the contribution of the newborn's distinct immune response to age-dependent susceptibility to infectious diseases has important implications for efforts to protect newborns from infection and entails review of the immunologic environment of pregnancy and the ontogeny of fetal and neonatal immunity (Kollmann et al., 2017). The unique functions of fetal, neonatal, and maternal immunity reflect adaptation to developmental challenges such as preservation of fetal well-being as an allogeneic graft versus adequate immunologic protection in the extrauterine environment. These immunologic transitions are regulated by a number of incompletely understood developmental and genetic mechanisms. The diversity and importance of these mechanisms are suggested by the heterogeneity and frequency of neonatal infections. Differences in immunologic responsiveness between newborns and adults are not defects or abnormalities but rather highly regulated ontogenic differences that facilitate transitions between distinct age-specific challenges. Just as the ductus arteriosus, a cardiopulmonary necessity in the intrauterine environment, closes at different rates in different infants, there is

variability in the pace at which developmentally and genetically programmed human fetal and newborn immunity changes from graft preservation to identification and destruction of invading pathogens.

Maternal and Placental Immunology

Immunologic tolerance to the growing fetus is a prerequisite for a successful pregnancy. The maternal–fetal interface is a dynamic site that encompasses multiple cellular interactions in an environment rich in cytokines and hormones. While immune mechanisms need to be in place to defend against microbial invasion (von Rango, 2008; Aagaard et al., 2014), the placenta is typically programmed to protect the fetus from rejection by the maternal immune system (Aluvihare et al., 2004; von Rango, 2008).

Several distinct but complementary innate and adaptive immune mechanisms contribute to the commensal immunologic relationship between the mother and the fetus throughout pregnancy (Fig. 36.1 and Table 36.1). Local (placental) and systemic (circulatory) factors mediate maternal tolerance to the fetus (Aluvihare et al., 2004). For example, human trophoblasts do not express conventional major histocompatibility complex (MHC) class I human leukocyte antigen (HLA)-A or HLA-B molecules, likely contributing to reduced alloantigenic recognition at the fetal–maternal interface. Human trophoblasts express HLA-C, principally during the first trimester of pregnancy (King et al., 1996a), and two nonclassical HLA molecules, HLA-E and HLA-G. HLA-G class Ib is expressed on extravillous cytotrophoblast and endothelial cells of fetal vessels in the chorionic villi as well as in amnion cells and amniotic fluid (Le Bouteiller et al., 1999; Rebmann et al., 2014). Unlike classical MHC molecules, HLA-G does not have a significant role in stimulating CD8⁺ T cells via the T-cell receptor (TCR) complex. Rather, the principal function of HLA-G molecules expressed by the trophoblast appears to be modulation of the activity of natural killer (NK) cells. HLA-G has additional immunomodulatory properties, including inhibition of activity of cytotoxic T cells, inhibition of alloproliferative responses by CD4⁺ T cells, and modulation of dendritic cell (DC) maturation and function (Carosella et al., 2008). These data reveal that the unique MHC class I molecule expression pattern on fetal trophoblast constitutes an intricate mechanism for orchestrating the activity of immune cells.

• **Fig. 36.1** Immunology of the Fetomaternal Interphase. While competent immune cells and bacteria can enter the fetomaternal interphase, multiple complex immune interactions are in place during healthy pregnancy to balance immune defense with immune tolerance between the mother and the allogeneic fetus. Several distinct but complementary innate and adaptive immune mechanisms contribute to the commensal immunologic relationship that exists between the mother and the fetus throughout pregnancy. In humans the decidua represents the uterine implantation site, where maternal blood flows into the intervillous space, “bathing” fetus-derived villous trees composed primarily of cytotrophoblasts. The surface of these villi consists of multinucleate syncytiotrophoblasts mediating nutrient and gas exchange between maternal and fetal tissues. The villi are directly exposed to circulating maternal immune cells. However, these cells do not recognize fetal tissue as “foreign” mainly because human trophoblasts lack classical class I and class II antigens and instead express human leukocyte antigen G (HLA-G). HLA-G and pregnancy hormones suppress natural killer (NK) cell and macrophage function and induce a bias of CD4⁺ T cells toward T_H2-type cytokine secretion. Dendritic cells are present in small numbers during pregnancy in decidual tissue but show impaired migration to draining uterine lymph nodes (entrapment). Regulatory T (Treg) cells specific to the fetus increase in number in the mother during gestation, and cells maintaining tolerance to fetal antigen can rapidly expand during a subsequent pregnancy. The role of exposure to microbial antigens in fetal immune priming seems important, but the exact mechanism is still being explored.

Other local factors contributing to maternal–fetal tolerance include selective degradation of tryptophan by the inducible enzyme indoleamine 2,3-dioxygenase inhibiting T-cell proliferation (Munn et al., 1998) and engagement of the proapoptotic molecule Fas on maternal lymphocytes by its ligand (FasL) on interstitial trophoblast cells (Hammer et al., 1999). FasL is expressed in both maternal and fetal components of the uteroplacental unit throughout gestation. Activated T cells express the Fas receptor, which delivers an apoptotic (death) signal when bound by FasL. Therefore expression of FasL limits the reciprocal migration of activated fetal and maternal T cells. Mice with a nonfunctional FasL demonstrate leukocyte infiltration and necrosis at the decidual–placental border,

TABLE 36.1 Selected Local and Systemic Factors Mediating Maternal Tolerance to the Fetus

| Factor | Function |
|--|---|
| Expression of nonclassical HLA molecules (e.g., HLA-G) | Inhibition of NK cells, CD4 ⁺ T cells, and cytotoxic T cells, and modulation of dendritic cell maturation and function |
| Indoleamine 2,3-dioxygenase | Depletes tryptophan and prevents T-cell proliferation |
| Fas ligand | Apoptosis of activated fetal and maternal T cells |
| Programmed death 1 and its ligand | Negative regulator of T-cell responses |
| Galectins | Apoptosis of activated fetal and maternal T cells |
| Decay-accelerating factor | Control of complement activation |
| Cytokines | T _H 2 bias prevents immune activation |
| Decidual macrophages | Suppressing immune activation |
| Decidual NK cells | Suppressing immune activation |
| FoxP3 ⁺ regulatory T cells | Suppressing immune effector cells (e.g., in response to paternal antigens) |

Microbiome Balanced immune response

FoxP3, Forkhead box P3; *HLA*, human leukocyte antigen, *NK*, natural killer.

with many resorption sites and small litters (Hunt et al., 1997). Progesterone-induced blocking factor is an immunomodulatory molecule released in response to progesterone by trophoblasts (Anderle et al., 2008). Its properties include indirect suppression of NK-cell function and inducement of bias of CD4⁺ T cells toward T_H2-type cytokine secretion (Szekeres-Bartho and Wegmann, 1996).

Galectins are expressed in human placenta primarily by the syncytiotrophoblast early in pregnancy (Than et al., 2009). On cell surface contact, galectins downregulate the cellular immune response, in part by inducing programmed cell death (apoptosis) of T lymphocytes (Liu and Rabinovich, 2010).

On a cellular level, DCs, an important type of antigen-presenting cell (APC) critical for cellular and humoral immune responses, play a prominent role in organ transplant rejection. The potential deleterious actions of DCs against the fetus may be curtailed by at least two factors: the progressive decline of decidual DC tissue densities shortly after implantation and impaired migration from decidual tissue to draining uterine lymph nodes. This entrapment of DCs during pregnancy may be a combined result of disappearing lymphatic vessels during decidualization (Volchek et al., 2010) and stromal cell–based processes limiting chemokine-directed cell migration (Collins et al., 2009). Other important cellular factors that may limit a potential immune reaction toward the fetus include the immunosuppressive phenotype of decidual macrophages (Gustafsson et al., 2008) and decidual NK cells.

Complement inhibition is essential for normal pregnancy in a murine model of antiphospholipid syndrome, an autoimmune condition characterized by thrombosis, thrombocytopenia, and recurrent fetal loss. In this model, fetal injury results from placental

inflammation initiated by local dysregulation of complement proteins. Both complement activation and fetal loss can be prevented by administration of anticoagulants with complement-inhibitory properties such as heparin but not by anticoagulants lacking complement-binding properties (Girardi et al., 2003, 2004). Some but not all human clinical interventional studies using anticoagulants with complement-binding properties to prevent fetal loss in antiphospholipid syndrome have suggested benefit (Di Nisio et al., 2005). Control of complement activation during human pregnancy is achieved by expression of decay-accelerating factor, membrane cofactor protein, and CD59 (protectin) on the trophoblast membrane (Denny et al., 2013), as well as high reproductive tract and systemic prostaglandin E_2 levels contributing to maternal immune tolerance to the fetus (Parhar et al., 1988).

In addition to local components, systemic elements are in place to maintain immune tolerance at the maternal–fetal interface. Abatement of certain autoimmune diseases during pregnancy (de Man et al., 2008) and an increased risk of infections (Jamieson et al., 2006) provide evidence for a more generalized immunosuppressive state during pregnancy (Poole and Claman, 2004). Although the precise mechanisms underlying this phenomenon are incompletely characterized, several reproductive hormones may play critical roles. For example, a relatively large study demonstrated that 48% of patients with at least moderate disease activity of rheumatoid arthritis showed signs of remission in the first trimester of pregnancy, while approximately 40% had a disease flare-up in the postpartum period (de Man et al., 2008). The rate of relapse in multiple sclerosis declines during pregnancy (Confavreux et al., 1998), and treatment with pregnancy levels of estradiol significantly reduced enhancing lesions on brain imaging (Camras et al., 1992). In addition, estrogen (17β -estradiol) in concentrations typically expressed during normal pregnancy augments forkhead box P3 (FoxP3) expression and expansion of T regulatory (Treg) cells in vitro and in vivo (Polanczyk et al., 2004; Tai et al., 2008).

T cells and T-cell–derived cytokines play a central role in immune regulation and inflammation. T_H1 cells are involved in cellular

immunity and rejection and are characterized by production of interleukin (IL)-2, interferon gamma (IFN- γ), and tumor necrosis factor alpha (TNF- α). In contrast, T_H2 cells are mediators of humoral immunity and produce IL-4, IL-5, and IL-13. Traditional dogma holds that a bias in T-cell cytokine secretion toward T_H2 -type cytokines and away from T_H1 -type cytokines is an immunologic condition necessary for maintaining healthy pregnancy (Dealtry et al., 2000). For example, IL-10 is a pregnancy-compatible cytokine that plays a vital role in maintaining immune tolerance (Cheng and Sharma, 2015). Significant shifts in the T_H1/T_H2 balance have been associated with various immune-mediated pregnancy complications. However, the emerging role of NK cells and emerging cytokines such as IL-12, IL-15, IL-18, IL-19, and IL-20 question the T_H1/T_H2 paradigm as oversimplified (Chaouat et al., 2004; Menon et al., 2006). For example, a subset of CD4 T cells that produce IL-17A and IL-17F, called T_H17 cells, may be involved in rejection of the fetus (Wang et al., 2010).

Role of Regulatory T Cells in Pregnancy

The discovery of a distinct lineage of T lymphocytes with dominant immunosuppressive properties (Brunkow et al., 2001) enabled major breakthroughs in understanding the mechanisms, whereby adaptive allogeneic responses against paternal antigens are actively suppressed during pregnancy. This type of Treg cell is characterized by expression of a lineage-specific transcription factor, FoxP3 (Fig. 36.2). On activation via their antigen-specific TCR, Treg cells are capable of suppressing immune effector cells, including DCs and effector T cells through a variety of mechanisms (Tang and Bluestone, 2008), thereby preventing a fatal form of autoimmune disease throughout life (Kim et al., 2007). Treg cells and T_H17 cells are two distinct lymphocyte subsets with opposing actions and share a complex relationship. Treg cells have a role in suppressing autoimmune responses and preventing the rejection of the fetus, and a decrease in Treg cell number is associated with miscarriage. In contrast, T_H17 cells promote inflammation, transplant rejection, and

• **Fig. 36.2** Forkhead Box P3–Positive Regulatory T-Cell Subpopulations and Their Development. Most human regulatory T (Treg) cells in peripheral blood originate from the thymus and are typically called *natural Treg* (nTreg) or *thymus-derived Treg cells* (1). Treg cells can originate from naive T cells in the periphery and are induced to express the identifying transcription factor forkhead box P3 (FOXP3) under the influence of transforming growth factor beta (TGFβ), at least in vitro (2). The Treg cells are often called *induced Treg* (iTreg) cells. Most Treg cells in the intestinal mucosa are thought to be iTreg cells originating from naive T cells in the mucosal immune system under the influence of specific antiinflammatory dendritic cells (CD103⁺ dendritic cells), TGFβ, and retinoic acid (3). The iTreg cells play an important role in pregnancy maintenance. DC, Dendritic cell.

autoimmunity, and increases in T_H17 cell numbers and decreases in Treg cell numbers are associated with recurrent miscarriage (Wang et al., 2010a, 2010b; La Rocca et al., 2014). The numbers of Treg cells specific to the fetus increase in the mother during gestation, and cells maintaining tolerance to fetal antigen can rapidly expand during subsequent pregnancy (Rowe et al., 2012). Paternal antigens may induce expansion of Treg cells, likely contributing to maternal tolerance to the allogeneic fetus (Zenclussen et al., 2005). Maternal and fetal Treg cells are essential in promoting fetal survival by avoiding the recognition of paternal semiallogeneic tissues by the maternal immune system (Mold et al., 2008; La Rocca et al., 2014).

The interaction between the costimulatory molecule programmed death 1 (PD1) and its ligand (PDL1) plays important roles in maintaining tolerance at the fetomaternal interface. PDL1 is expressed on the trophoblasts of the placenta, and PD1 is expressed on the maternal effector T cells and Treg cells. PDL1 expression maintains Treg cell/effector T-cell ratios and suppresses increases in the number of T_H17 cells (D'Addio et al., 2011). Blockade of PDL1 signaling in animal models results in fetal rejection (Guleria et al., 2005). The role and ontogeny of fetal Treg cells is discussed more fully in the section entitled Adaptive Immunity.

Role of the Microbiome

The paradigm of a sterile uterus postulates that the fetus develops free of bacteria and antigenic agents (Mackie et al., 1999). However, bacteria can be cultured from amniotic fluid and fetal tissues in pregnancies complicated by preterm labor even without rupture of membranes (Goldenberg et al., 2000). Bacterial DNA can be detected in meconium and umbilical cord blood (UCB) of healthy neonates as well as amniotic fluid obtained by cesarean section and placentas following undisturbed, healthy pregnancies without histologic evidence for chorioamnionitis. The exact mechanisms by which bacteria pass from the mother to the fetus are being investigated. Increased bacterial translocation from the intestine to other organs can be found during pregnancy, and bacterial DNA signatures can be detected in the peripheral blood of pregnant women (Perez et al., 2007). Placental bacteria resemble most closely the human oral microbiome (Aagaard et al., 2014), suggesting hematogenous bacterial transfer. While not yet widely accepted in humans, maternal microbial transmission to the fetus is a universal phenomenon in animals, likely constituting an essential evolutionary act of symbiosis (Funkhouser and Bordenstein, 2013).

Globally, these studies imply a possibly critical role of maternal bacteria to inform normal immune development of the developing fetus. While the importance of fetal programming has been well described for cardiovascular and metabolic diseases, it is now also discussed in the context of environmentally influenced immune-mediated diseases. A possible reason for the initial exposure of bacterial molecular patterns to the fetus in utero is to prime the immune system and/or the epithelium to respond appropriately to pathogens and commensals after birth (Abrahamsson et al., 2015). For example, maternal exposure to farm animals during pregnancy was associated with greater Toll-like receptor (TLR) gene expression and lower risk of atopic sensitization in children (Ege et al., 2006). Similar protective effects against atopic sensitization were observed after dietary interventions during pregnancy, such as maternal supplementation with fish oil (Dunstan et al., 2003) or probiotics (Elazab et al., 2013). In contrast, antibiotic use in pregnancy was associated with asthma during the fifth year of life (Benn et al., 2002).

The exact mechanism of prenatal immune priming is unknown, but in an experimental asthma model, microbial exposure to pregnant mice resulted in epigenetic changes in promoter regions of cytokines associated with an allergic phenotype-increased expression of IFN- γ and reduced expression of IL-4, IL-5, and IL-13 (Furuya et al., 1990). This concept has been confirmed in human studies where exposure to farms during pregnancy has been associated with increased DNA demethylation of the FoxP3 locus and increased number and function of Treg cells in UCB cells (Schaub et al., 2009).

While exposure to commensal bacteria during pregnancy seems beneficial for a healthy developing immune system, inflammatory states during pregnancy can have long-lasting adverse effects on the offspring. For example, in murine models, maternal immune activation can trigger autism-like behavior and neuropathology in the offspring (Hsiao et al., 2013). Despite the importance of immune regulation for a healthy pregnancy and recent scientific advances, much remains to be learned regarding the molecular mechanisms used by the fetal immune system to promote tolerance or suppression.

Effect of Pregnancy Complications on the Developing Fetal Immune System

To enable initiation and maintenance of pregnancy, the intrauterine environment significantly shapes the developing immune system as is evident from the antiinflammatory cytokine profile and protection from atopic sensitization in offspring after maternal exposure to farming activities and farm dairy products during pregnancy (Ege et al., 2008; Pfefferle et al., 2010). This effect is at least in part mediated through an increase in the number of fetal Treg cells (Schaub et al., 2009).

In contrast, fetal exposure to inflammation during critical developmental windows can influence immune programming to augment inflammatory neonatal responses. Histologic chorioamnionitis (HCA) is a common complication of pregnancy, typically caused by intrauterine bacterial infection and defined by inflammation of the fetal membranes. Fetal exposure to HCA induces immune activation, resulting in fetal inflammatory response syndrome (FIRS), and shapes the neonatal transcriptomic immune response (Weitkamp et al., 2016). The clinical characteristics of FIRS consist of systemic inflammation and elevation of fetal plasma IL-6 and other proinflammatory cytokine levels (Gomez et al., 1998). Long-term sequelae of the sustained systemic inflammation precipitated by fetal exposure to HCA include blindness (Chen et al., 2011), cerebral palsy (Wu et al., 2000), impaired cardiac function (Romero et al., 2004), lung disease (Kramer et al., 2009), and disruption of normal fetal immune development (Leviton et al., 2011; O'Shea et al., 2012; Savasan et al., 2012; Bastek et al., 2014; Kallapur et al., 2014). In humans, placental infection, chorioamnionitis, or villitis together with a fetal inflammatory response appear to increase the risk of surgical necrotizing enterocolitis (NEC) (Moore et al., 2013).

Studies of fetal sheep and human UCB have demonstrated activation of the adaptive immune system following exposure to HCA. In a model of chorioamnionitis and FIRS caused by administration of intra-amniotic lipopolysaccharide (LPS) in rhesus monkeys at approximately 80% of gestation, fetal Treg cell generation in the thymus was inhibited, while the concentration of proinflammatory cells in the spleen increased (Rueda et al., 2016). The immunologic changes associated with endotoxin-induced systemic and organ-specific immune priming in the fetus can be

mimicked by administration of IL-1 α or IL-1 β , suggesting a possibly important role of IL-1 receptor signaling in FIRS. In a similar model using intra-amniotic injection of LPS 7 or 14 days before preterm delivery in fetal sheep, involution and activation of the fetal thymus with structural organ changes was observed (Kuypers et al., 2012). Furthermore, UCB derived from human neonates with clinical evidence of perinatal infection exhibited a higher proportion of T_H1 cells than UCB from uninfected neonates (Matsuoka et al., 2001).

Overall, epidemiologic and experimental data point to the central role of maternal immune activation and/or FIRS in the pathogenesis of many immune-mediated complications of prematurity such as chronic lung disease, brain damage, retinopathy of prematurity, gut injury, and behavior abnormalities. On the other hand, prenatal immune activation may improve vaccine responses and render the newborn more resistant to infectious challenges later in life (Strunk et al., 2012).

Developmental Fetal–Neonatal Immunology

Newborn and young infants, especially those born preterm, are at increased risk of developing a range of bacterial and viral opportunistic infections. This age-dependent susceptibility is in part based on immune ontogeny (Dowling and Levy, 2014). In the past few decades research has focused on the molecular, cellular, and functional bases for immunologic differences between newborns and older individuals, which we discuss as they relate to innate and adaptive immunity.

Innate Immunity

During fetal/newborn adaptation from the intrauterine environment to the colonization of skin and mucosal surfaces following birth, the innate immune system shields the newborn from infection while orchestrating the acquisition of protective adaptive immune responses (Levy, 2007). These innate mechanisms evolve across gestation and postnatal age (Fig. 36.3) and include protective barriers such as the vernix caseosa, which contains antimicrobial proteins and peptides (APPs) and microbicidal fatty acids (Tollin et al., 2005), developmentally controlled functional regulation of TLR signaling (Kollmann et al., 2012), expression of acute-phase reactants (Levy, 2007; Fig. 36.4) and complement proteins, and alterations in neutrophil and monocyte function (Forster-Waldl et al., 2005; Levy et al., 2006). Importantly, functional maturation of innate immunity enables colonization with commensal organisms while limiting potentially dangerous inflammatory responses (Kollmann et al., 2017). Herein we discuss key features of innate immunity in early life beginning with soluble-based defense systems that progress to leukocyte-based defense systems.

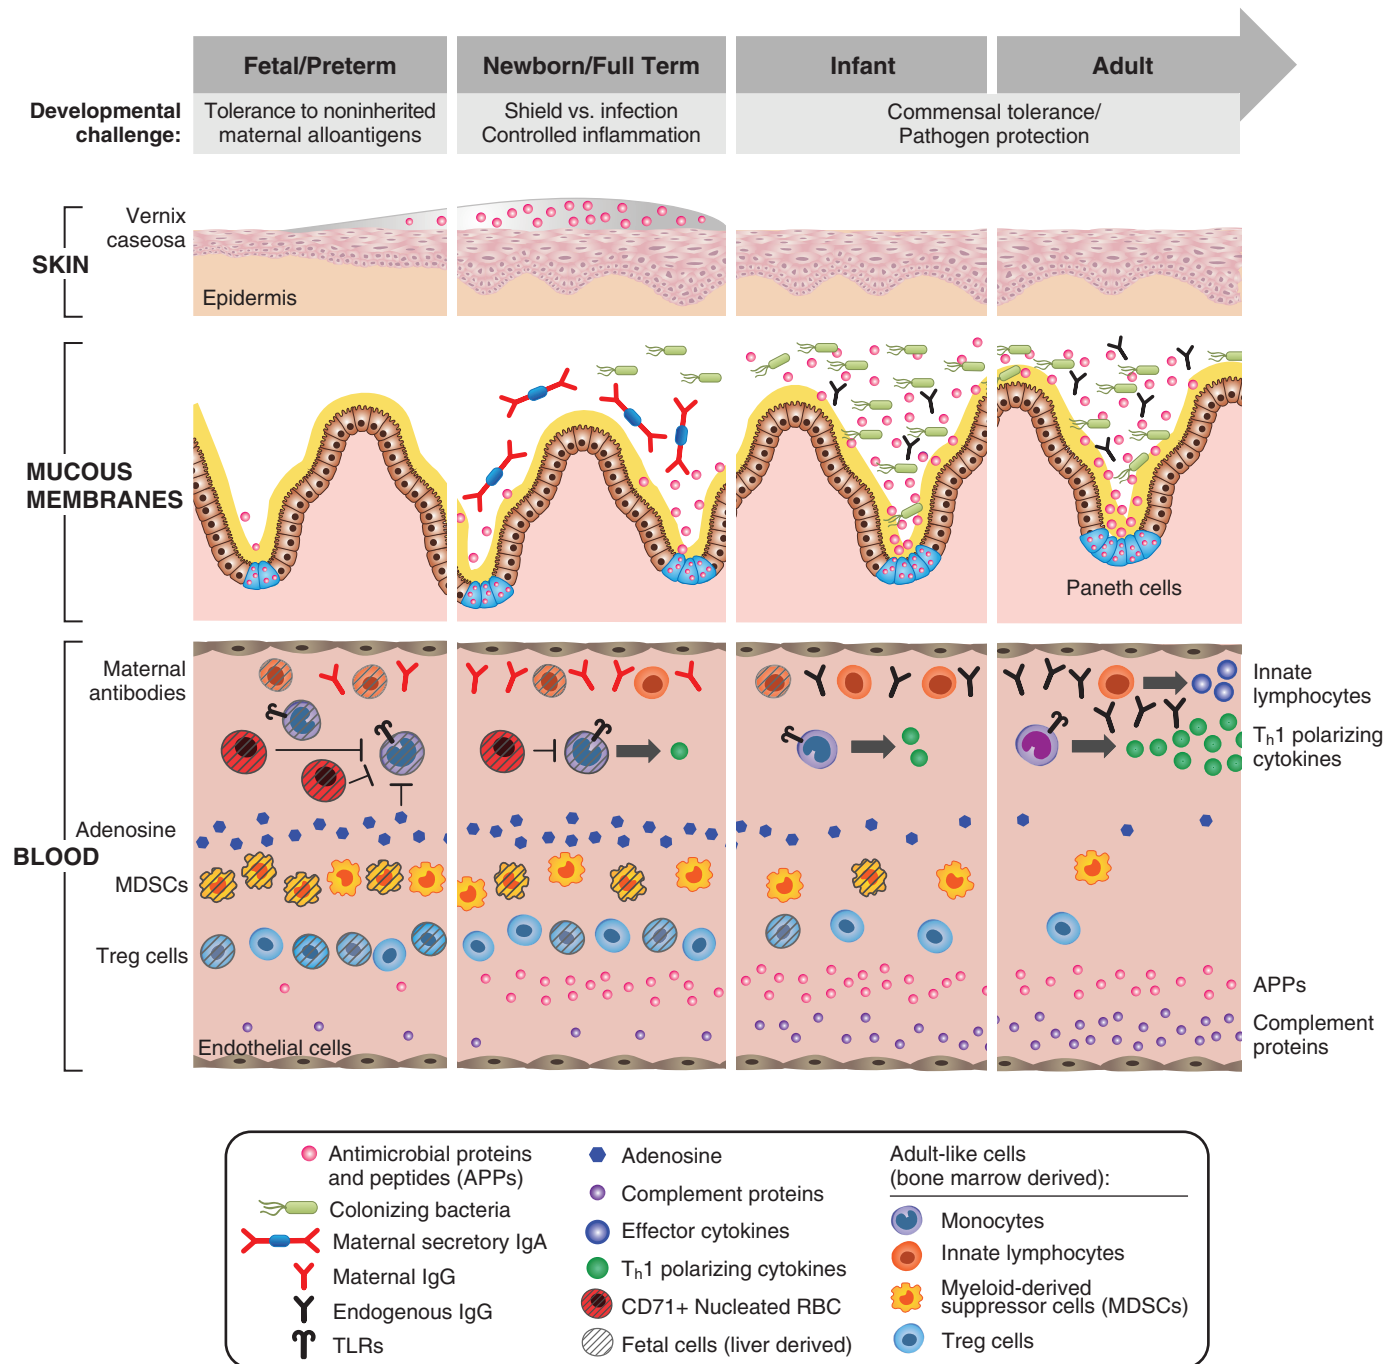

Complement

Central to the innate immune response is the complement system that consists of more than 40 plasma, cell surface, and regulatory proteins that interact to regulate multiple physiologic functions, including resistance to pyogenic infections, interaction between innate and adaptive immunity, and elimination of immune complexes, products of inflammatory injury, and apoptotic self cells (Zipfel and Skerka, 2009). Components of the complement system recognize and lyse bacteria, opsonize microorganisms, release anaphylatoxins, solubilize immune complexes, and induce B-cell proliferation and differentiation.

Activation of the complement cascade occurs via three pathways—classical, lectin, or alternative (Thiel, 2007; Zipfel and Skerka, 2009). Several characteristics of the complement cascade are important for fetal–neonatal immunity. First, the complement system features both antibody-dependent specificity via the classical pathway activation triggered by interaction of antigens with antibodies, and antibody-independent activation of the alternative and lectin pathways initiated by pathogen-associated structures such as endotoxin and polysaccharides. Thus for the fetus or infant who has not received from the mother or has not yet produced antigen-specific immunoglobulin (Ig) G for immunologic recognition, the alternative and lectin pathways may be critical for triggering the effector functions of the complement cascade (Kielgast et al., 2003; Simister, 2003). Second, the enzymatic activation of the complement cascade enables rapid functional amplification: deposition of a single Ig molecule or C3b fragment can generate enzymatic cleavage of thousands of later-acting components and thus multiple complement activities (Carroll, 2004; Zipfel and Skerka, 2009). In addition, the alternative pathway can be amplified via a positive feedback activation mechanism, because C3b, an activation product of the alternative pathway C3 convertase, is a component of this convertase (Janssen et al., 2006). As the fetus and newborn are particularly dependent on antibody-independent pathogen recognition for immunologic responsiveness, the positive amplification loop of the alternative pathway may be particularly critical for rapid generation of complement effector functions in early life in the absence of antibody-based recognition. Third, the continuous activation of the alternative pathway requires rigorous regulation in the fetus to avoid tissue damage during organ remodeling (Zipfel et al., 2007). Finally, the contributions of the lectin pathway to fetal–neonatal complement activation and fetal well-being are still under investigation.

Studies of fetal and neonatal complement have focused on quantification of serum concentrations of individual components, examining maternal–fetal transport of these proteins, assessing specific effector functions of the classical and alternative pathways, and investigating contributions of complement activation to common neonatal diseases. Detectable concentrations of C3 (1% of adult levels) and C1 inhibitor (20% of adult levels) can be measured as early as 5 to 6 weeks' gestation (Gitlin and Biasucci, 1969). By 26 to 28 weeks' gestation, both C3 and C1 inhibitor concentrations increased to 66% of adult levels. Functionally and immunochemically measured classical and alternative pathway protein concentrations in UCB increase with advancing gestational age, such that impairment in CH50 is particularly evident in the preterm (Grumach et al., 2014), and at full-term gestation the concentrations are only approximately 50%–75% of adult concentrations (Wolach et al., 1997; Sonntag et al., 1998). Although neonatal UCB lectin pathway component concentrations are lower than those in older children and adults, the correlation between mannose-binding lectin (MBL) and gestational age has not been consistently observed (Hilgendorff et al., 2005; Swierko et al., 2009). Of note, on the basis of studies of genetically determined, structurally distinct complement variants in maternal and umbilical cord serum, no transplacental passage from the mother to the fetus of C3, C4, factor B, or C6 has been observed (Colten et al., 1981).

Much remains to be learned regarding regulation of complement effector functions in the fetus and newborn. Activation of the alternative pathway or the lectin pathway enables opsonization of invading microorganisms without specific Ig recognition. Accordingly, for preterm infants or those without organism-specific maternal IgG, alternative or lectin pathway activation provides a

• **Fig. 36.3** Ontogeny of Skin, Soluble, and Cellular Innate Defense Systems. Host-protective barrier functions include physical, chemical, and functional components of the skin and mucous membrane epithelia of the fetus, neonate (birth to 28 days of age), and infant (1 month to 1 year of age). Skin: while physical and chemical barriers are impaired in early in life, especially in the preterm newborn, the vernix caseosa and skin epithelia of full-term newborns robustly express antimicrobial proteins and peptides (APPs). Mucous membranes: in parallel with and induced by an increasingly complex microbiota, the newborn intestinal mucosal epithelium rapidly changes structurally, with an increase in the population of crypts and crypt-based Paneth cells, as well as functionally with increasing APP expression. Blood: the composition of neonatal blood is distinct, with relatively low concentrations of complement components and APPs and high concentrations of the immunosuppressive purine metabolite adenosine. Plasma also contains maternal antibodies that are transferred beginning midgestation and supplemented by postnatal factors derived from breast milk. Innate immunity is detectable from the end of the first month of gestation, with changes driven largely by the increasing exposure to environmental microbes. Neonatal antigen-presenting cells such as blood monocytes express pattern recognition receptors (e.g., Toll-like receptors, *TLRs*) with distinct functional responses, including limited T_H1-polarizing cytokine production, to most stimuli. Adaptive immunity develops from 4 weeks of gestation onward, with changes driven by an evolving chimerism reflecting fetal (liver-derived, *shaded cells*) regulatory T (*Treg*)-cell-rich lymphocytes, and more adultlike (bone marrow derived, *unshaded cells*) lymphocytes with distinct epigenetically encoded functional programs. *Ig*, Immunoglobulin; *RBC*, red blood cell. (Modified from Kollmann TR, Kampmann B, Mazmanian SK, Marchant A, Levy O. Protecting the newborn and young infant from infectious diseases: lessons from immune ontogeny. *Immunity*. 2007;46:350–363.)

• **Fig. 36.4** Innate Detection, Signaling, and Effector Functions of Blood Phagocytic Leukocytes and Hepatocytes. Innate immune signals are detected via signaling loops. Monocytes express pattern recognition receptors, including C-type lectin receptors (CLRs), CD14, and Toll-like receptors (TLRs). TLR-mediated monocyte activation engages signaling pathways resulting in kinase and nuclear factor κ B (NF- κ B) pathway activation, culminating in inflammatory gene transcription, including generation of cytokines that amplify an antiinfective response. For example, interleukin (IL)-1 β and IL-6 engage cognate cytokine receptors on hepatocytes, inducing acute-phase response, including production and secretion of lipopolysaccharide (LPS)-binding protein (LBP), mannose-binding lectin (MBL), the pentraxin C-reactive protein (CRP), and soluble CD14 (SCD14). These molecules recognize and modulate inflammatory activity of microbial products. For example, LBP at low concentrations delivers LPS to TLR4, thereby enhancing signaling but at higher LBP concentrations detoxifies LPS by delivering it to plasma lipoproteins. Monocyte production of tumor necrosis factor (TNF) activates neutrophils that deploy antimicrobial systems that are oxygen dependent, such as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, as well as those that are oxygen independent, such as membrane-active antimicrobial proteins and peptides, including defensins and bactericidal/permeability-increasing protein (BPI), an LBP homologue that binds to and neutralizes endotoxin. Soluble mediators, such as the antiinflammatory purine metabolite adenosine, can limit proinflammatory responses. cAMP, Cyclic adenosine monophosphate; C/EBP- α , CCAAT/enhancer binding protein; NOD2, nucleotide-binding oligomerization domain-containing protein 2; RelA, NF- κ B subfamily protein; RIG-1, retinoic acid-inducible gene 1.

critical mechanism for engaging complement effector functions (Super et al., 1989; Maruvada et al., 2008; Swierzko et al., 2009). The functional contribution of the classical pathway to effector functions has been assessed through the use of blood-mediated opsonophagocytosis by polymorphonuclear leukocytes of group B streptococci (GBS) type Ia (Edwards et al., 1983). This GBS serotype may be opsonized by classical pathway components in

the absence of specific antibodies and thus enables characterization of classical pathway function. In 8 of 20 neonatal serum samples examined, decreased bactericidal activity was detected and correlated with significantly lower functional activity of C1q and C4. These studies did not determine whether this decrease was mediated by an inhibitor of function or by an intrinsic change in functional activity of these components in neonatal sera. Studies of MBL

concentrations and pathway activity suggest a contribution of the lectin pathway to neonatal susceptibility to infection (Super et al., 1989; Sumiya et al., 1991; Thiel et al., 1995; Kilpatrick et al., 1996; Kielgast et al., 2003; Swierczko et al., 2009). Complement regulatory proteins (e.g., C4b-binding protein and factor H) also contribute to neonatal susceptibility as suggested by the failure of neonatal serum to reduce invasion by GBS and *Escherichia coli* into human brain microvascular endothelial cells (Maruvada et al., 2008). In vitro experiments in which killing of *E. coli* by neonatal serum samples was limited by C9, but not by other classical pathway components, suggest that this terminal complement component is apparently important for cytolysis of this pathogen (Lassiter et al., 1992, 1994). Although relatively lower concentrations of complement components likely contribute to poor control of bacterial replication, these complement concentrations are nevertheless sufficient, via C3- and factor B-dependent activity in the alternative pathway, to enhance GBS-induced production of TNF- α by monocytes in human newborn UCB tested in vitro (Levy et al., 2003).

In addition to relatively low serum concentrations of classical, alternative, and lectin pathway complement proteins, additional complement functions important for fetal and neonatal well-being can contribute to reduced capacity to activate the classical and alternative pathways. For example, fetal and neonatal serum demonstrates reduced concentration of C4b-binding protein, a critical regulator of classical pathway C3 convertase activity (Malm et al., 1988; Melissari et al., 1988; Moalic et al., 1988; Fernandez et al., 1989). Lower C4b-binding protein concentration increases the functional anticoagulant activity of protein S, with which it complexes and thereby contributes to decreased coagulation function of the fetus and newborn. Consideration of complement components that also express nonimmunologic functions will likely be important in characterizing developmental regulation of complement component production.

Complement activation contributes to tissue injury in several common neonatal diseases, including neonatal hypoxic-ischemic encephalopathy, NEC, meconium aspiration syndrome, and intrauterine growth restriction and fetal loss (Girardi and Salmon, 2003; Lassiter, 2004; Schultz et al., 2005; Girardi et al., 2006; Mollnes et al., 2008; Schlupbach et al., 2008). Unregulated complement activation may occur in selected infants undergoing extracorporeal membrane oxygenation therapy, raising concern for inflammatory injury on that basis (Johnson, 1994; Kozik and Tweddell, 2006). C5a is present in the cerebrospinal fluid of human newborns, at especially high concentrations in those born preterm (Pataky et al., 2016), raising the possibility that complement activation in the neonatal brain may contribute to preterm brain injury.

Overall, study of the complement system in early life, including characterization of the developmental and genetic regulation of this important group of plasma and cell surface proteins, promises to shed further light on immune ontogeny in relation to health and disease.

Antimicrobial Proteins and Peptides

The human body expresses natural antibiotics, including APPs that act alone and in combination with endogenous (e.g., complement) and exogenous (e.g., conventional antibiotic) systems to prevent infection and/or eliminate invading microorganisms (Levy, 2004). APPs are expressed by a range of cells, including epithelial cells and leukocytes, especially neutrophils (see Fig. 36.4), and are found associated both with cells and in plasma. Plasma levels of

APPs vary with gestational age such that preterm plasma is relatively deficient in multiple APPs, likely contributing to reduced microbicidal capacity (see Fig. 36.3; Battersby et al., 2016). Examples of APPs include (1) lactoferrin, an 80-kDa protein with iron-binding and direct membrane perturbing properties found in tear fluid, saliva, and neutrophil secondary granules, (2) the 5-kDa bactericidal/permeability-increasing protein, expressed on certain mucosal epithelia as well as neutrophil primary granules, with high affinity for LPS that enables it to neutralize the inflammatory activity of endotoxin and targets its microbicidal activity toward gram-negative bacteria, (3) 14-kDa phospholipase A₂, an acute-phase reactant expressed in liver with ability to enzymatically kill a range of gram-positive pathogens, and (4) 4-kDa disulfide-rich defensin peptides of neutrophil primary (azurophilic) granules with broad microbicidal activity (Levy, 2004). Ongoing efforts are aimed at developing congeners of APPs as novel antiinfective agents for individuals who are relatively APP deficient, including preterm infants and those undergoing chemoradiotherapy (Palmer et al., 2011). For example, oral administration of lactoferrin to human preterm newborns has shown promise in reducing the incidence of sepsis and NEC (Pammi and Abrams, 2015).

Innate Lymphoid Cells, Including Natural Killer Cells

Innate lymphoid cells (ILCs) are derived from a common lymphoid progenitor, are defined by the absence of antigen-specific B-cell receptors (BCRs) or TCRs, and do not express myeloid or DC markers (Klose and Artis, 2016). ILCs are divided into subgroups based in part on the cytokine profile they produce: (1) group 1 ILCs produce IFN- γ and are functionally dependent on the transcription factor T-bet; (2) group 2 ILCs produce type 2 cytokines (e.g., IL-4, IL-5, IL-9, and IL-13) in response to helminth infection and are dependent on ROR α and GATA3; and (3) group 3 ILCs produce IL-17A and/or IL-22 and are dependent on the transcription factor ROR γ t.

NK cells are the most studied of the ILCs. These group 1 ILCs constitute approximately 10%–15% of all peripheral blood lymphocytes. They are present in the spleen, lungs, and liver and are also rarely found in lymph nodes and thoracic duct lymph (Cerwenka and Lanier, 2001). NK cells represent up to 70% of all lymphocytes in the maternal decidual tissue (King et al., 1996b). They demonstrate distinct morphology, function, and surface molecule expression, including expression of CD16 (Fc gamma receptor [F γ R]III) and CD56 (nerve cell adhesion molecule 1). Mature NK cells appear larger and more granular than T or B cells (Cooper et al., 2001) and express both activating and inhibitory receptors that are used to selectively identify and kill virally infected cells and tumors (Biassoni et al., 2001). The presence of MHC class I molecules on potential target cells induces signals that suppress NK-cell function. MHC class I-deficient target cells activate NK-cell function, triggering release of lysosomal granules containing serine proteases, perforin, and transforming growth factor beta (TGF- β), thereby disrupting the target cell membrane and inducing an inflammatory response. Fetuses and neonates demonstrate reduced NK-cell activity compared with adults (Georgeson et al., 2001; Kadowaki et al., 2001).

NK cells are derived from a common hematopoietic progenitor that retains T-cell and B-cell developmental potential (Boos et al., 2008). NK cells first make their appearance in fetal liver as early as 6 weeks' gestation. Committed CD34⁺CD56⁺ NK cell progenitors have been identified in the fetal thymus, bone marrow, and liver. In the human neonate, the NK-cell population is immature: only half of all NK cells express CD56, and the NK-cell cytolytic activity

is lower (Dominguez et al., 1998). This functional reduction in NK-cell activity may contribute to the severity of neonatal herpes simplex virus (HSV) infections. Profound defects in NK-cell activity result in familial hemophagocytic lymphohistiocytosis (HLH), a disease characterized by fever, hepatosplenomegaly, cytopenia, hyperferritinemia, and hemophagocytosis. Familial HLH arises from mutations in genes that encode proteins involved in the granule-exocytosis pathway and can be fatal without bone marrow transplant (Orange, 2006; Jordan and Filipovich, 2008).

NK-cell receptors are fundamentally different from TCRs and BCRs. NK-cell receptor gene expression does not require gene segment rearrangement, and the receptors are not clonally distributed. Instead, NK cells use an array of stimulatory and inhibitory receptors to regulate their cytolytic functions (Lanier, 2008). A cluster of 10 or more genes encoding killer-cell Ig-like receptors (KIRs) is located on human chromosome band 19q13.4 (Biassoni et al., 2001). Each of these type I glycoproteins recognizes a different allelic group of HLA-A-, HLA-B-, HLA-C-, or HLA-G-encoded proteins, and each KIR is expressed by only a subset of NK cells. Another family of Ig-like receptor genes termed *ILT* is present near the KIR locus at 19q13.3. These receptors are not as restricted as the KIRs and bind multiple HLA class I molecules. A third inhibitory receptor gene locus is on chromosome band 12p12-p13, encoding a C-type lectin inhibitory heterodimeric receptor called *CD94/NGK2* that binds HLA-E. Those KIRs, ILT receptors, and *CD94/NGK2* molecules with long cytoplasmic tails and two immunoreceptor tyrosine-based inhibitory motifs (ITIMs) function as inhibitory receptors. On phosphorylation, the two ITIMs recruit and activate the Src homology domain 2 (SH2)-containing phosphatases, which turn off the kinase-driven activation cascade (Ravetch and Lanier, 2000). The KIR family member KIR2DL4 is distinct from other KIRs in structure and distribution. KIR2DL4 binds HLA-G and has a single ITIM in the cytoplasmic tail and a lysine in the transmembrane region, enabling association with adaptor proteins. This inhibitory receptor was found on all decidual NK cells in the placenta at term but not on circulating maternal NK cells, suggesting that expression of KIR2DL4 is induced during pregnancy (Rajagopalan and Long, 1999).

Other KIRs or members of the C-type lectin receptor superfamily are activating receptors (Moretta et al., 2001). These receptors lack the long cytoplasmic tail of the inhibitory receptors and therefore do not contain ITIMs. Instead, they have a charged amino acid in the transmembrane region that enables receptor association with the adaptor molecule DAP12 (Lanier et al., 1998). This adaptor contains an immunoreceptor tyrosine-based activation motif (ITAM) that allows these receptors to activate NK cells. The physiologic role of these HLA class I-specific activating receptors remains unknown. NK cell-activating receptors also include *natural cytotoxicity receptors* (NKp46, NKp30, NKp44), proteins that are Ig superfamily members with little similarity to one another or to other NK-cell receptors (Moretta et al., 2001). These receptors are highly specific for NK cells and apparently interact with non-HLA molecules.

CD244 (2B4) is a member of the signaling lymphocyte activation molecule (SLAM) family of receptors expressed on all human NK cells (Ma et al., 2007). On interaction with the ligand CD48 on target cells, NK-cell signaling proceeds via interactions between the immunoreceptor tyrosine-based switch motif (ITSM) (switch motif) in the cytoplasmic tail of CD244 and one of two SH2 domain-containing adaptor proteins, SLAM-associated protein (SAP) and Ewing sarcoma-associated transcript 2 (EAT-2). SAP interactions trigger activation, as

evidenced in humans with X-linked lymphoproliferative disease, caused by loss-of-function mutations in the SAP linker. In the absence of SAP, interactions with EAT-2 may be inhibitory (Lanier, 2008).

Recent studies have explored the potential contribution of ILCs beyond NK cells. A role for lung group 2 ILCs in mediating respiratory syncytial virus (RSV)-induced IL-33-driven T_H2 -biased immunopathology has been demonstrated in neonatal mice (Saravia et al., 2015). IL-23-responsive group 3 ILCs played a role in the pathogenesis of neonatal intestinal inflammation in a murine model (Chen et al., 2015). Much remains to be learned regarding the ontogeny of ILC function with respect to both the quantity and the quality of these cells in the very young.

Polymorphonuclear Neutrophils

Neonatal polymorphonuclear neutrophils (PMNs) are present at early stages of gestation, but their functional capacities are different from those of adult PMNs. Progenitor cells that are committed to maturation along granulocyte or macrophage cell lineages (granulocyte-macrophage colony-forming units) are detectable in the human fetal liver between 6 and 12 weeks' gestation in similar proportions as in adult bone marrow (Christensen, 1989). Human fetal blood has detectable granulocyte-macrophage colony-forming units from 12 weeks' gestation to term (Christensen, 1989). Although these progenitor cells are detectable in the fetus and newborn, developmental differences between adult and mature neonatal PMNs have been demonstrated—in signal transduction, cell surface protein expression, cytoskeletal rigidity, rolling adhesion, microfilament contraction, transmigration oxygen metabolism, intracellular antioxidant mechanisms, and neutrophil extracellular trap formation (Hill, 1987; Carr, 2000; Henneke and Berner, 2006; Levy, 2007; Yost et al., 2009). The magnitude of PMN functional differences correlates with the maturity of the infant and begins to decrease within the first few weeks after birth (Carr, 2000).

In addition to intrinsic age-dependent differences in PMN function, age-dependent cell extrinsic soluble factors may developmentally regulate induction of specific functions and maturation of these cells (Christensen, 1989; Pettengill et al., 2014). For example, low concentrations of the chemoattractant complement component C5a in neonatal sera might impair establishment of chemoattractant gradients at sites of inflammation. In addition, elevated concentrations in human neonatal blood plasma of adenosine (Pettengill et al., 2013), an endogenous purine metabolite that acts via seven-transmembrane adenosine receptors to inhibit inflammatory leukocyte responses, could contribute to inhibition of newborn neutrophil function.

Systemic bacterial infection in newborns is frequently accompanied by profound neutropenia, prompting investigation of neutrophil kinetics in infected infants (Santos et al., 1980; Christensen et al., 1982). These studies have suggested diverse, developmentally specific regulatory mechanisms required for mobilization of the neutrophil response to infection. The absence of detectable neutrophil precursors in bone marrow aspirates of infected infants and systemic neutropenia motivated studies of neutrophil replacement therapy in neutropenic, infected infants (Christensen et al., 1980). Although this approach has been successful in some cases, the results have not been uniformly beneficial, and a Cochrane review suggests a need for adequately powered multicenter trials of granulocyte transfusions in neutropenic septic neonates (Pammi and Brocklehurst, 2011). Metaanalysis suggesting that granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor may reduce mortality in

newborns when systemic infection is accompanied by severe neutropenia requires confirmation in adequately powered trials (Carr et al., 2003). Heterogeneity in the impact of neutrophil modulation may reflect the importance of individualizing immunologic interventions for the genetic background, developmental stage, and pathogenic microorganism being treated.

Monocytes, Macrophages, and Dendritic Cells

Cells committed to phagocyte maturation, including granulocyte or monocyte-macrophages, are detectable in the human fetal liver by 6 weeks' gestation and in peripheral fetal blood by 15 weeks' gestation. Unlike granulocytes, whose tissue half-life is hours to days, macrophages migrate into tissues and reside for weeks to months. In a tissue-specific fashion, these cells regulate availability of multiple factors, including proteases, antiproteases, prostaglandins, growth factors, reactive oxygen intermediates, and a range of cytokines and chemokines. Importantly, monocytes can migrate from the bloodstream to tissue sites, becoming tissue-based DCs. Monocytes, macrophages, and DCs share the ability to present antigens to T lymphocytes, thereby triggering the classic adaptive immune responses.

Compared with their adult counterparts, newborn monocytes, macrophages, and DCs demonstrate reduced chemotaxis and phagocytosis as well as distinct TLR signaling that is polarized toward T_H2 and antiinflammatory cytokine production (Kollmann et al., 2012). The distinct function of newborn APCs reflects both intrinsic characteristics, including reduced nucleosome remodeling for IL-12 p70 production (Goriely et al., 2004) as well as the modulatory effects of age-specific extrinsic factors such as the antiinflammatory purine metabolite adenosine, the level of which is relatively elevated in human newborn UCB plasma (Pettengill et al., 2013, 2014).

A growing literature documents that stimulation of monocytes results in a change in innate "setpoint" such that responses to subsequent stimuli are altered (Saeed et al., 2014). This phenomenon, reflecting adaptive features of the innate immune system that are mediated by epigenetic changes, has been termed *trained immunity* (Netea and van der Meer, 2017) and may contribute to the heterologous beneficial ("nonspecific") effects of live attenuated vaccines (Goodridge et al., 2016). Much remains to be learned regarding the scope, ontogeny, and mechanisms underlying innate training/innate memory.

Adaptive Immunity

Antigen-specific T and B lymphocytes bearing TCRs and BCRs, respectively, play multiple critical roles in adaptive immunity. T cells responding to a specific antigen secrete cytokines and kill infected target cells and tumor cells by cell-mediated cytotoxicity. These functions of CD4 and CD8 T cells depend on their TCRs specifically recognizing antigenic peptides bound to MHC molecules. Several T-cell populations have a more restricted expression of TCRs that recognize ligands other than peptide/MHC ligands and have an innate-like role early in the immune response; these include NK T (NKT) cells, mucosal-associated invariant T (MAIT) cells, and T cells expressing $\gamma\delta$ TCRs ($\gamma\delta$ T cells). As already discussed in the section entitled Role of Regulatory T Cells in Pregnancy, CD4⁺ Treg cells serve as negative regulators of effector responses. Analogously, antigen-specific B cells can be divided into populations that are involved in the conventional immune response and that depend on CD4 T-cell help for their differentiation into antibody-secreting cells; those that have an innate immunity-like

function and act early in immune responses, such as marginal zone B cells; and those with regulatory-like suppressive function ("Breg cells").

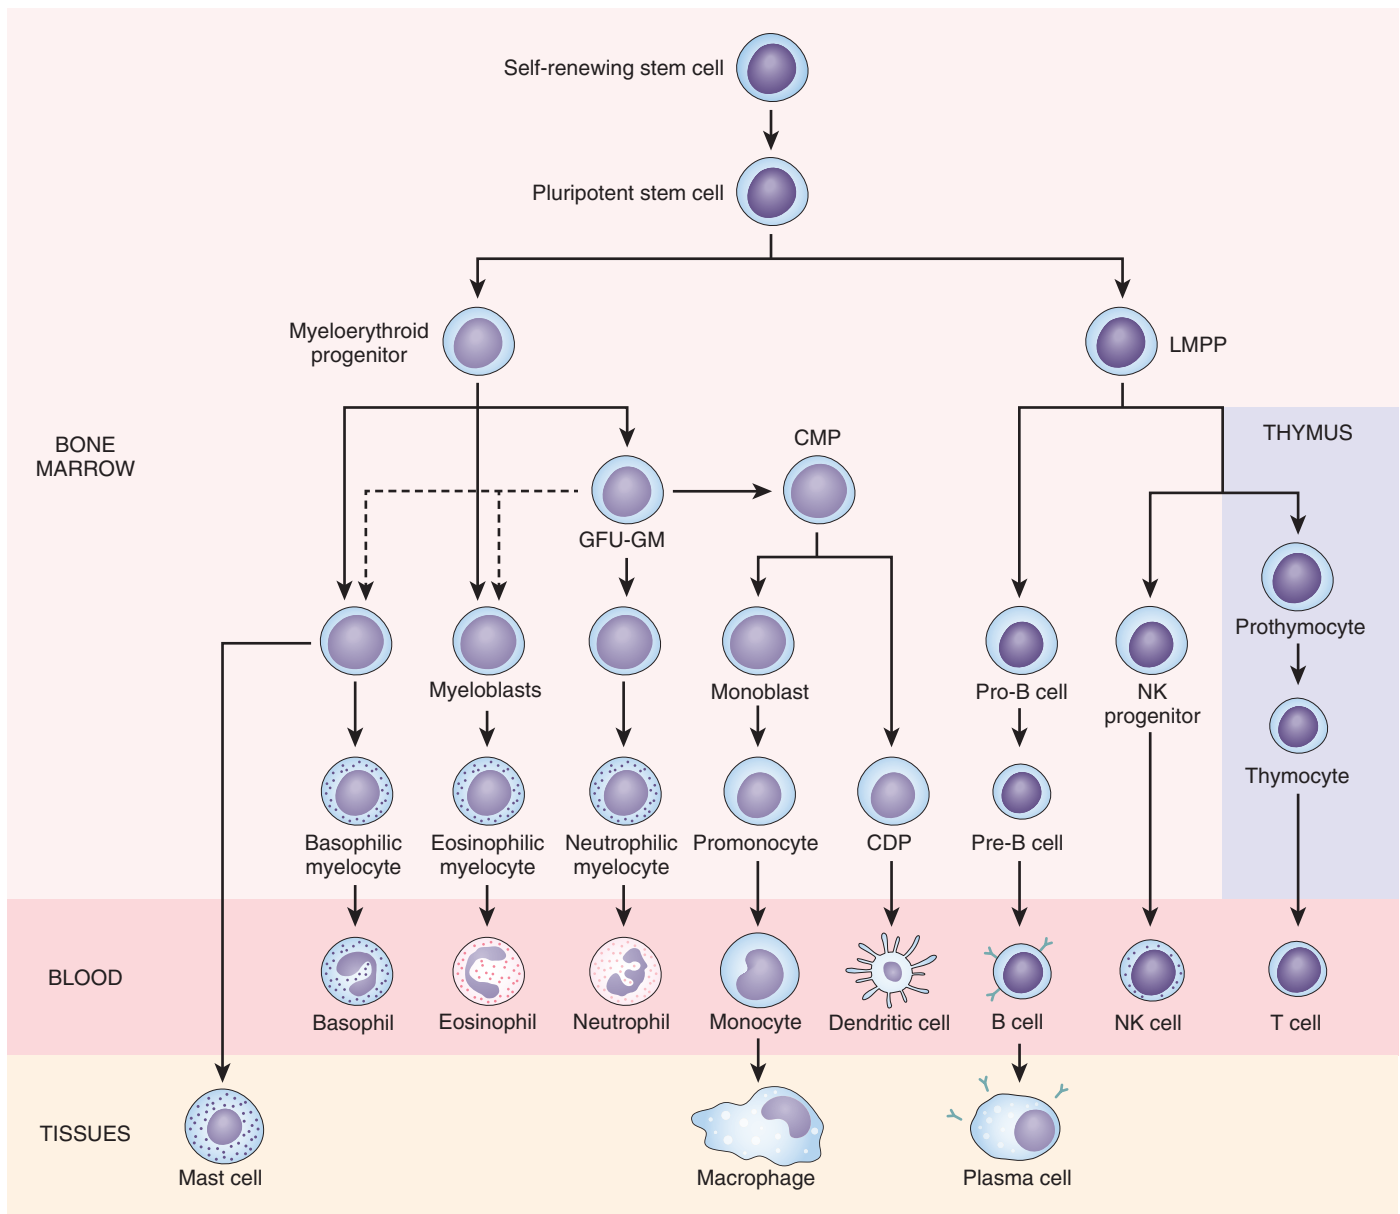

All major lymphocyte lineages, which include T cells, B cells, and ILCs, which lack antigen-specific receptors and include NK cells (Hazenberg and Spits, 2014), develop from CD34⁺CD38^{dim} pluripotent hematopoietic stem cells (HSCs) found in the fetal liver and bone marrow in a perivascular niche (Chen et al., 2016; Fig. 36.5). The process of lymphocyte differentiation and hematopoiesis in general has been traditionally viewed as a linear progressive narrowing of differentiation potential based on the sequential expression of specific transcriptional regulators. However, recent work indicates that the pathways of development of the human myeloid, erythroid, and megakaryocyte lineages may undergo major shifts during ontogeny. For example, in fetal liver, the HSCs and their CD34⁺CD38⁺ progenitor cell derivatives have a similar ratio of cells with multipotent versus unilineage potential, whereas in bone marrow, which is the definitive site of hematopoiesis starting in the second trimester of gestation, CD34⁺CD38⁺ progenitor cells predominantly have unilineage potential (Notta et al., 2016). Another example is that the HSCs of UCB have a greater potential to differentiate into the T lineage than HSCs of adult bone marrow (De Smedt et al., 2011).

T Lymphocytes

Thymocyte Development

Most T cells develop in the thymus, which includes cell types of nonhematopoietic origin, such as epithelial cells, as well as multiple cell types of hematopoietic origin, including the developing immature T cells or thymocytes, DCs, mononuclear phagocytes, and small numbers of B cells. The thymic epithelial cells are derived from the third branchial cleft and the third or fourth branchial pouch, a process that is perturbed in DiGeorge syndrome, resulting in thymic epithelial hypoplasia. Thymic lobes can be divided into four regions, which, going from outward to inward, are the subcapsular region, cortex, corticomedullary junction, and medulla. Prothymocytes, which are bone marrow-derived CD34⁺CD38⁺CD62L⁺ lymphoid cells, have the capacity to commit to the T-cell or other lymphocyte lineages depending on their receipt of instructive signals (Spits, 2002). Circulating prothymocytes enter the thymus via vessels at the cortical-medullary junction. The prothymocyte becomes committed to the T-cell lineage by the engagement of its surface notch 1 receptor by ligands displayed on the thymic epithelium, such as delta-like ligand 4. This engagement leads to the surface expression of CD1 and its differentiation into a pro-T cell that migrates to the subcapsular region just below the outer capsule.

The subcapsular pro-T cell expresses all of the internal proteins required for V(D)J recombination, including the recombinase activating gene (RAG) 1 and RAG2 endonucleases that make double-stranded breaks in DNA; the proteins involved in nonhomologous end joining repair (e.g., Artemis, XLF [Cernunnos], and DNA ligase IV); and those that are essential for generating junctional diversity at complementarity determining region (CDR) 3 (e.g., terminal deoxynucleotidyl transferase [TdT]). CDR3, which is the most variable in amino acid sequence, is located at the center of the antigen-specific binding site of both TCRs and BCRs. The pro-T cell lacks most cell surface proteins characteristic of mature peripheral T cells, including CD3, CD4, and CD8, and is therefore also referred to as a *triple-negative thymocyte* (Fig. 36.6). The pro-T cell is the first stage in which there is VDJ rearrangement of TCR gene loci, with the TCR γ gene rearrangement occurring most frequently

• **Fig. 36.5** Myeloid and Lymphoid Differentiation in the Bone Marrow, Blood, and Tissues. CDP, Committed dendritic cell progenitor; CFU-GM, colony-forming unit granulocyte-macrophage; CMP, common myeloid progenitor; LMPP, lymphoid primed multipotent progenitor; NK, natural killer.

(Sherwood et al., 2011). If this rearrangement is productive (i.e., capable of expressing a full-length TCR γ chain protein) and the thymocyte subsequently undergoes a productive TCR δ gene rearrangement, a $\gamma\delta$ TCR heterodimer is expressed on the cell surface, allowing the thymocyte to differentiate into a mature $\gamma\delta$ T cell that emigrates from the thymus into the periphery. More frequently (>95% of the time) these TCR γ and/or TCR δ gene rearrangements are nonproductive, and the pro-T cell attempts TCR β chain gene rearrangement. If this arrangement is productive, the TCR β chain is expressed on the cell surface in association with an invariant pre-T alpha chain forming the pre-TCR complex, which defines the pre-T-cell stage of development. Like the mature TCR, the pre-TCR is associated with the CD3 complex of proteins, which includes CD3 γ , CD3 δ , CD3 ϵ , and CD3 ζ chains, all of which have cytoplasmic tails containing specific amino acid sequences called ITAMs. These ITAMs serve

as molecular targets for tyrosine phosphorylation and binding by tyrosine kinases, such as Lck and zeta chain-associated protein of 70 kDa (ZAP-70), which generate intracellular signals leading to the induction of target genes (Lopez-Rodriguez et al., 2015). These signals direct the pre-T cell to (1) proliferate, (2) upregulate expression of CD4 and CD8 and become a double-positive (CD4⁺CD8⁺) thymocyte, (3) migrate from the subcapsular area to the thymic cortex, and (4) start rearrangement of the TCR α chain gene locus (see Fig. 36.6).

Rearrangement of the TCR α chain gene by CD4⁺CD8⁺ thymocytes is a two-step process in which there first is an internal deletion of a $\psi\delta$ rec segment that brings the unrearranged V α segments in close proximity with J α segments and the C α constant region (Hazenbergh et al., 2001). The intervening DNA, which is excised as a circular product with fused signal joint sequences,

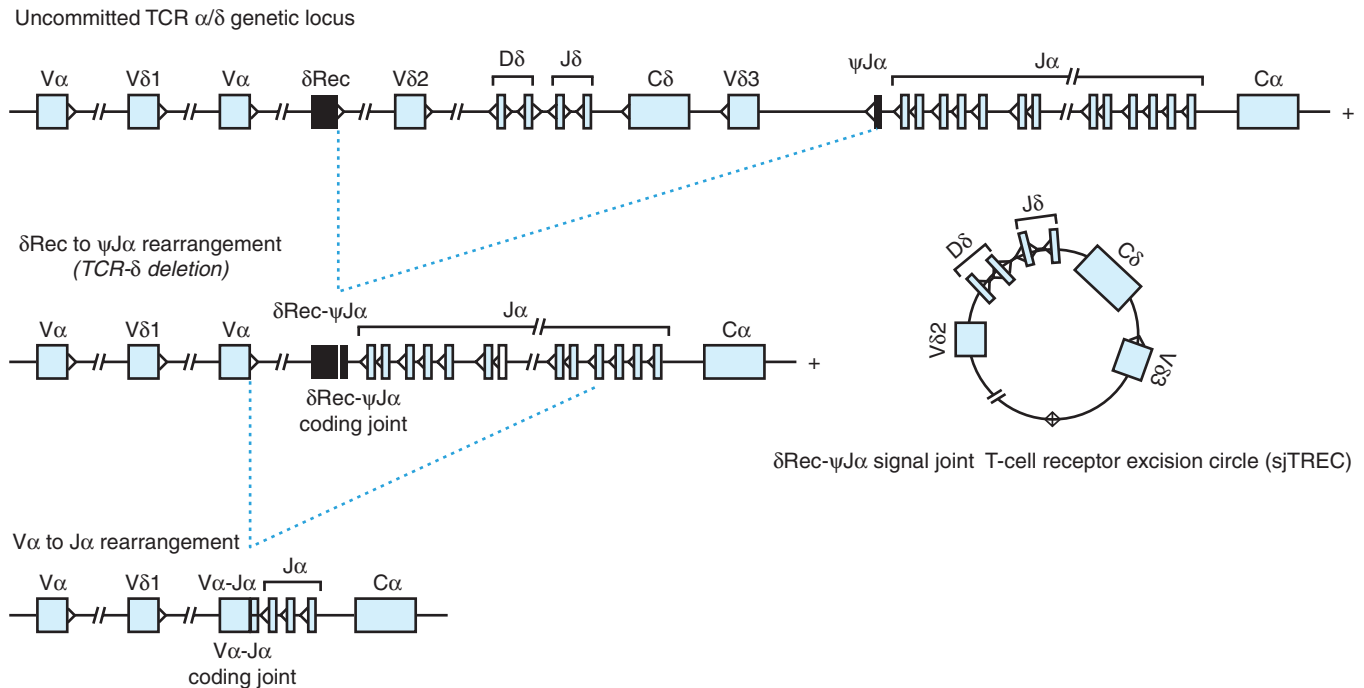

• **Fig. 36.6** Stages of Human $\alpha\beta$ T-Cell Receptor-Positive Thymocyte Development. Prothymocytes from the bone marrow or, before the third trimester, fetal liver, which express CD34, CD38, and CD62 ligand (CD62L), but lack CD4, CD8, or CD3/T-cell receptor (TCR), enter the thymus via vessels at the junction between the thymic cortex and medulla. They differentiate to progressively more mature $\alpha\beta$ TCR⁺ thymocytes, defined by their pattern of expression of the $\alpha\beta$ TCR-CD3, CD4, CD8, and CD38. Protein tyrosine kinase 7 (PTK7) is expressed throughout thymocyte development. The TCR β chain gene and then the TCR α chain gene are rearranged in the outer cortex. Positive selection occurs mainly in the central thymic cortex by interaction with thymic epithelial cells that express major histocompatibility complex (MHC) class I and class II proteins, and negative selection occurs mainly in the medulla by the interaction with thymic dendritic cells that display MHC associated with self-peptides that are derived from medullary thymic epithelial cells. Following these selection processes, medullary thymocytes emigrate into the circulation and colonize the peripheral lymphoid organs as CD4 and CD8 T cells with high levels of $\alpha\beta$ TCR/CD3. These recent thymic emigrants (RTEs) also have a high content of signal joint TCR excision circles (sjTRECs), which are a circular product of TCR gene rearrangement (see Fig. 36.7). In adults, most RTEs have modest levels of surface expression of PTK7 but probably lack CD38. In contrast, in neonates, most peripheral T cells have high levels of surface expression of PTK7 and CD38 and have relatively high amounts of sjTRECs compared with adult peripheral T cells.

referred to as a *signal joint TCR excision circle* (sjTREC), is highly stable within the cell (Fig. 36.7). The sjTREC content of the T-lineage cell subsequently decreases mainly as a result of cell proliferation, which under normal conditions is minimal until the mature T cell undergoes antigen activation-induced clonal proliferation. Thus the measurement of the sjTREC content by peripheral blood T cells is an indirect but useful assessment of the adequacy of production of new T cells by the thymus. The measurement of sjTRECs in neonatal blood spots is routinely used for newborn screening in the United States for identifying infants with impaired

production of T cells by the thymus as occurs in most forms of severe combined immunodeficiency (SCID) (see [Specific Immunologic Deficiencies of the Newborn and Their Diagnosis](#)).

Double-positive thymocytes that have productive TCR α chain gene rearrangements replace their pre-TCR with a TCR consisting of an $\alpha\beta$ TCR heterodimer in association with the CD3 proteins (see Fig. 36.6). The next major checkpoint of thymocyte development is positive selection, in which the $\alpha\beta$ TCR of the CD4⁺CD8⁺ thymocyte is tested for whether it has significant affinity for either the MHC class I alleles (HLA-A, HLA-B, and HLA-C in humans)

• **Fig. 36.7** Sequential rearrangements in the T-cell receptor (TCR) α/δ genetic loci generate signal joint TCR excision circles (sjTRECs) and $V\alpha$ - $J\alpha$ rearrangements. Rearrangement of the δ Rec segment to the $J\alpha$ segment commits the thymocyte to the $\alpha\beta$ TCR lineage as this deletes the C and J segments that are necessary to encode a productive TCR δ chain. The δ Rec- $\psi J\alpha$ rearrangement also generates an sjTREC, which is commonly used for monitoring peripheral T-cell populations for their recent thymic origin. The δ Rec- $\psi J\alpha$ rearrangement and excision of an sjTREC are followed by TCR α ($V\alpha$ - $J\alpha$) rearrangements, which if productive result in expression of an $\alpha\beta$ TCR/CD3 complex on the thymocyte cell surface. Most thymocytes that express $\alpha\beta$ TCRs have molecular evidence of nonproductive rearrangements of portions of the TCR δ gene locus (not shown).

or the MHC class II alleles (HLA-DR, HLA-DP, and HLA-DQ in humans) expressed by thymic cortical epithelial (TCE) cells. All MHC class I and class II molecules during their biosynthesis have peptides loaded into their peptide-binding grooves. In the absence of infection or vaccination with foreign proteins, these peptides are derived from self-proteins, as is the case for the MHC of TCE cells. Murine studies indicate that specialized MHC class I-binding peptides may be generated by a special type of proteasome expressed by TCE cells (the thymoproteasome) and that these play an important role in increasing the antigen responsiveness of mature peripheral T cells (Takada et al., 2015). In positive selection, thymocytes with TCRs that are unable to bind to MHC/peptide complexes on TCE cells with sufficient affinity to generate intracellular signals die by apoptosis, the default pathway. In cases where the TCR binding to MHC generates a relatively weak to moderate signal, the thymocyte is positively selected for survival. A large range of from relatively weak to medium strength “analog” signals are converted by the intracellular signaling protein Themis into a single “digital” outcome of thymocyte survival and maturation (Gascoigne and Acuto, 2015).

CD4⁺CD8⁺ thymocytes with TCRs that receive MHC class II/peptide survival signals lose CD8 expression and upregulate CD3 expression, thereby becoming CD4⁺CD8⁺ thymocytes that are CD3^{high}. CD4⁺CD8⁺ thymocytes also begin to acquire a gene expression pattern characteristic of mature peripheral CD4 T cells that is required for their capacity to carry antigen-induced effector functions, such as IL-2 secretion and CD40-ligand (CD40L) expression. CD4⁺CD8⁺ thymocytes with TCRs that receive MHC

class I/peptide survival signals lose CD4 expression and upregulate CD3 expression, thereby becoming CD4⁺CD8⁺ thymocytes; they also begin to express genes that are characteristic of peripheral CD8 T cells and that are required for their antigen-induced capacity to become cytotoxic cells. These CD4⁺CD8⁺ thymocyte-specific versus CD4⁺CD8⁺ thymocyte-specific outcomes of positive selection are directed by the master transcription factors ThPOK and Runx3, respectively (Taniuchi, 2016). In cases where the TCRs of CD4⁺CD8⁺ thymocytes receive very high levels of signaling, double-positive cortical thymocytes undergo apoptosis (Hogquist and Jameson, 2014).

A small subset of thymocytes bearing TCR α chains containing the $V\alpha 24J\alpha 18$ segments in association with TCR β chains containing $V\beta 11$ segments interact with relatively high affinity with CD1d, an MHC class I-like protein that is expressed on double-positive thymocytes (Van Kaer et al., 2016). This TCR interaction leads to the thymocyte-positive selection for NKT-lineage cells, which are distinct in function from conventional T cells in having the ability to rapidly secrete large amounts of cytokines, such as IFN- γ and IL-4, during the early phase of innate immune responses to pathogens (Brigl et al., 2011).

Another subset of thymocytes bearing TCR α chains with $V\alpha 7.2J\alpha 33$ segments paired with TCR β chains using either $V\beta 2$ or $V\beta 13$ interact with high affinity with an MHC class I-like protein, MR1, on hematopoietic cells, resulting in the positive selection of MAIT cells (Martin et al., 2009). MAIT cells, which are predominantly CD8 single positive, are found in mucosal tissues, such as the intestine, lung, and liver (Liuzzi et al., 2015).

Positively selected single-positive CD4⁺CD8⁻ or CD4⁻CD8⁺ thymocytes move into the medulla, where they undergo a final selection process before emigrating from the thymus as CD4 and CD8 T cells called *negative selection*. This selection process, which is an important mechanism for maintaining tolerance of T cells to peptides derived from self-proteins, involves the exposure of the mature thymocytes to medullary APCs expressing a highly diverse repertoire of peptides derived from self-proteins. These self-proteins include those that are normally expressed in a tissue-restricted manner (e.g., peptides derived from insulin, which is produced by pancreatic beta islet cells or parathyroid hormone) or that are characteristic of only certain stages of early development (Derbinski and Kyewski, 2010). This unusual pattern of protein expression by medullary DCs and B cells is the result of nuclear proteins, such as those encoded by the autoimmune regulator (De Martino et al., 2016) and Fezf1 (Takaba et al., 2015) genes, stochastically relieving the transcriptional repression of these tissue-specific and developmentally regulated genes. Thymocytes that have high levels of signaling for peptides derived from self-proteins are induced to undergo apoptosis, whereas intermediate levels of signaling by CD4⁺CD8⁻ thymocytes result in their differentiation into Treg cells (Perry and Hsieh, 2016). Thus thymically derived Treg cells have TCRs that have substantial affinity for self-proteins expressed in a tissue-specific or developmental-specific manner.

Recent Thymic Emigrants and the Naïve T-Cell Compartment

Following negative selection, single-positive mature thymocytes undergo additional maturation before exiting the thymus as recent thymic emigrant (RTE) naïve T cells, including upregulation of CC-chemokine receptor 7 (CCR7), IL-7 receptor alpha chain (CD127), L-selectin (CD62L), and Smad interacting protein 1 (Hogquist et al., 2015). In humans this maturation also includes downregulation of the CD45R0 isoform and upregulation of the CD45RA isoform of the CD45 protein tyrosine phosphatase. The fully mature thymocyte then enters the circulation as an RTE naïve T cell that is CD45RA⁺CD45R0⁻CCR7⁺CD62L⁺ and that retains surface expression of protein tyrosine kinase 7 (PTK7), a protein that is highly expressed during intrathymic development (Haines et al., 2009). The RTE naïve T cell recirculates between the peripheral lymphoid tissue and the blood. The entry of the circulating naïve T cells involves the interaction of T-cell surface adhesion molecules, such as L-selectin (CD62L) with sialomucins expressed on high endothelial venules and the T-cell CCR7 chemokine receptor with its chemokine ligands, which are expressed within peripheral lymphoid tissues. RTE naïve T cells also undergo postthymic antigen-independent maturation over a period of several months with the loss of PTK7, a decrease in the capacity for activation-induced chemokine (C-X-C motif) ligand 1 (CXCL8) (IL-8) production (van den Broek et al., 2016), and an increase in the capacity for IFN- γ production (Haines et al., 2009). PTK7⁺ RTE naïve T cells also undergo one to two homeostatic cell divisions as part of this maturation (Haines et al., 2009).

In the human embryo the first naïve, mature T cells appear in the circulation and lymphoid organs at approximately 11 to 12 weeks' embryonic development and have been found in the fetal intestine at 11 weeks' gestation (Spencer et al., 1986; Blom et al., 1998). Thymopoiesis continues at least through age 40 years as indicated by the presence of circulating PTK7⁺ RTEs (Haines et al., 2009) and by the results of in vivo metabolic labeling studies with deuterium (Vrisekoop et al., 2008). Thymectomy early in life (e.g., as part of open heart surgery for congenital heart disease

or for the treatment of certain autoimmune diseases, such as myasthenia gravis) results in a substantial loss of naïve T cells, including PTK7⁺ RTEs (Haines et al., 2009) and CXCL8-expressing RTEs (van den Broek et al., 2016). Thymectomy also results in an oligoclonal memory T-cell compartment (Prelog et al., 2009; Sauce et al., 2009). Some children who have undergone neonatal thymectomy appear to regenerate thymic tissue, which is associated with the reacquisition of naïve T cells with RTE features (van den Broek et al., 2016). In individuals who do not recover thymic function, the decay process is accelerated by chronic cytomegalovirus (CMV) infection, resulting in an immunosenescent T-cell phenotype similar to that seen in elderly individuals and associated with increased morbidity and mortality (Wikby et al., 2006). Naïve T cells of the peripheral lymphoid compartment can undergo homeostatic expansion in response to cytokines, such as IL-7, and this proliferation may be particularly important in disease states that impair the production of RTEs and result in profound peripheral lymphopenia, such as treatment with chemotherapy or human immunodeficiency virus (HIV) infection.

Naïve CD4 T-Cell Activation Into Effector T_h1, T_h2, T_h17, and Follicular Helper T Cells

Naïve T-cell activation requires a complex molecular signaling cascade that involves the reorganization of signaling molecules of the T-cell membrane into an "immunologic synapse" with the APCs bearing MHC/peptide (Smith-Garvin et al., 2009). For naïve T-cell activation, CD11c⁺ DCs are particularly effective as APCs. TCR engagement by a high-affinity MHC/peptide ligand results in phosphorylation of components of the CD3 complex associated with the $\alpha\beta$ TCR. The CD3 proteins contain cytoplasmic tails with specific amino acid sequences called ITAMs, which serve as molecular targets for the tyrosine kinase Lck. The CD3 ζ chain is thought to be the most critical component and is found as a homodimer. The tyrosine phosphorylated CD3 ζ chain binds the tyrosine kinase ZAP-70, which, in turn, phosphorylates linker for activation of T cells, a large protein that serves as a docking site for multiple signaling molecules. Full naïve T-cell activation also requires costimulation by engagement of CD28 on the T-cell surface by CD80 or CD86 on the APC. Together, signaling generated by the TCR and CD28 results in the activation of several parallel signaling pathways, including those of the calcineurin–NFAT, Ras–AP-1 (fos/jun), and protein kinase C delta–nuclear factor κ B (NF- κ B) pathways resulting in entry of the transcription factors nuclear factor of activated T-cells (NFAT), activator protein-1 (AP-1), and NF- κ B into the nucleus, where they bind to the *cis*-regulatory elements of hundreds of genes and alter their transcription (Smith-Garvin et al., 2009).

After their activation, naïve CD4 T cells differentiate into effector T_h1, T_h2, T_h17, or follicular helper T (T_h) cells (Zhu et al., 2010; Crotty, 2014). Differentiation into peripheral Treg cells can also occur, and these cells are discussed in the section entitled *Regulatory T Cells*. Each of these CD4 T cell types is defined by prototypical master transcription factors and by secretion of a characteristic profile of cytokines in response to antigenic stimulation and preferential expression of particular chemokine receptors. The cytokine milieu produced by non-T cells in the local environment during antigen presentation is a primary factor influencing the developmental fate of a naïve T cell following activation.

Activated T_h1 cells secrete IFN- γ , which is the signature T_h1 cytokine, IL-2, lymphotoxin α , and TNF- α , and also express surface CD40L (CD154). IL-12 produced by DCs and IFN- γ produced by NK cells promote T_h1 cell development by a signal transducer

and activator of transcription (STAT) 4-dependent mechanism, and this results in expression of the master transcription factor T-bet. T_H1 responses are generally proinflammatory, and IFN- γ secretion is particularly important in activating mononuclear phagocytes for the control of intracellular bacterial pathogens, such as *Mycobacteria*, *Salmonella*, and *Listeria*. IFN- γ also increases MHC expression, which may be particularly important in counteracting the attempt by herpesviruses to avoid antigen detection by their production of a number of proteins that decrease MHC class I and class II antigen presentation. Human neonatal CD4 T cells are biased against T_H1 polarization relative to adult T cells (Randolph and Lewis, 2006), and this bias may continue into infancy and contribute to the increased vulnerability of infants to severe and disseminated tuberculosis (Vanden Driessche et al., 2013). Both CD4 T cell–intrinsic mechanisms (Chen et al., 2006) and APC-intrinsic mechanisms, such as decreased expression of IL-12 p70 by neonatal and infant DCs (Goriely et al., 2001, 2004), appear to contribute to blunted T_H1 immunity.

Activated T_H2 cells secrete IL-4, IL-5, and IL-13 and are important in the response to infections with multicellular parasites, such as helminths, and classic allergic diseases in which the level of IgE is elevated. Their development is facilitated by a number of non-T-cell–derived cytokines, particularly from epithelial sources, including thymic stromal lymphopoietin (TSLP), IL-25, and IL-33, as well as IL-4 produced by basophils. This non-T-cell–derived IL-4 activates STAT6, which, in turn, induces GATA3, the master transcription factor for T_H2 differentiation from naïve CD4 T cells. The T_H2 cytokines IL-4 and IL-13 induce Ig heavy chain class switching to the IgE isotype (the T_H2 phenotype). IL-5 is an eosinophil growth factor and also promotes eosinophil survival in inflamed tissues. IL-13 promotes goblet cell hyperplasia and mucous secretion. Thus T_H2 cells coordinate many of the characteristic responses of the skin and mucosal tissues to parasitic infection and allergens. Murine neonatal CD4 T cells appear to be intrinsically biased toward T_H2 polarization (Adkins et al., 2004), but in vitro studies using human UCB CD4 T cells and adult allogeneic DCs as an APC source have not observed this bias (Chen et al., 2006).

Activated T_H17 cells secrete the closely related cytokines, IL-17A and IL-17F, which induce increased expression of defensins by the epithelium, leading to increased tissue resistance of the mucosa and skin to fungal and bacterial infection. In humans the most important role of IL-17 is to control mucocutaneous fungal infection, particularly with *Candida* (Okada et al., 2016). The differentiation of activated naïve CD4 T cells into T_H17 cells is promoted by IL-1 β and TGF- β and cytokines that activate STAT3, including IL-6 and IL-23. Activated STAT3 induces the expression of ROR γ , which is the master transcription factor for T_H17 cell differentiation (Bedoya et al., 2013). In addition to their role in host defense, T_H17 cells are also prominently involved in the pathogenesis of inflammatory bowel disease, psoriasis, multiple sclerosis, rheumatoid arthritis, and other autoimmune diseases. The ability of naïve CD4 T cells of the term or preterm neonate to differentiate into T_H17 cells appears to be robust (Black et al., 2012). This suggests that factors other than impaired CD4 T-cell T_H17 immunity contribute to increased susceptibility of the neonate and young infant to mucocutaneous candidiasis.

Activated T_H cells secrete IL-21 and also express surface CD40L, both of which provide essential signals for the activation and differentiation of B cells to produce antibody against protein antigens (Crotty, 2014). Human naïve CD4 T-cell differentiation into T_H cells appears to be promoted by the combination of IL-12, IL-21, IL-23, and TGF- β and engagement of inducible T-cell costimulator

(ICOS) on the T cell by ICOS ligand. Whether the differentiation of human neonatal naïve CD4 T cells into T_H cells is as robust as that of older children and adults is unclear. However, the observation that young infants, compared with older children, have reduced primary antibody responses to protein antigens, such as the hepatitis B vaccine (West, 1989), could be a reflection of less robust T_H cell generation following immunization.

Effector CD4 T-Cell Response to Herpes Simplex Virus Infection

Postnatal primary infection of the human neonate with HSV often results in high levels of the virus in blood with severe systemic disease and/or dissemination to the central nervous system. In contrast, these are rare events in infants older than 4 weeks, suggesting a unique age-related susceptibility that may reflect rapid postnatal maturation of key immunologic antiviral mechanisms. At least part of the vulnerability of the neonate may be due to limitations in HSV-specific CD4 T-cell immune responses, which are decreased and delayed for T_H1 cytokine production, compared with those adults with primary HSV infection (Burchett et al., 1992). HSV-specific antibody responses are also reduced and delayed in neonatal compared with adult primary HSV infection (Sullender et al., 1987), suggesting that neonatal HSV-specific T_H -cell generation may also be relatively impaired.

Naïve CD8 T-Cell Activation Into Cytolytic Effector Cells

Naïve CD8 T cells have a similar CD45RA⁺CD45R0[−]CD62L⁺CCR7⁺ surface phenotype as those of the CD4 T-cell subset and recirculate between the blood and secondary lymphoid tissue by the same mechanisms. As for naïve CD4 T cells, antigen presentation by CD11c⁺ DCs is particularly efficient for CD8 T-cell activation, which results in the acquisition of cytolytic effector function mediated by perforin and granzymes and the expression of FasL. Many activated CD8 T cells also secrete T_H1 cytokines, such as IFN- γ and TNF- α . Data on the ability of neonatal naïve CD8 T cells to differentiate into effector cells capable of cell-mediated cytotoxicity and eliminating infected target cells are limited. In cases of congenital CMV infection, robust CMV-specific fetal CD8 T-cell responses occur (Marchant et al., 2003), suggesting that this pathway for differentiation is intact with a strong source of antigenic stimulation. There is limited information on the neonatal and young infant CD8 T-cell responses to acute viral infection. Studies of older infants and young children indicate a relatively robust CMV-specific CD8 T-cell response to primary infection (Chen et al., 2004).

Antigen-Specific Memory T-Cell Responses

Memory T cells, which are generated as part of the primary antigen-specific T-cell response, are defined by function (i.e., more rapid effector response) and by expression of a CD45RA[−]CD45R0⁺ surface phenotype. A recently identified T memory stem cell (Tmsc) subset, which differentiates from naïve T cells early in the immune response, appears to play an important role in the long-term generation of antigen-specific CD4 and CD8 memory T cells (Gattinoni et al., 2017). This generation does not appear to require continued exposure of the Tmsc to antigen, accounting for the persistence of T-cell memory for decades following a single acute infection with pathogens that are completely cleared from the body. Tmsc give rise to central memory T cells, which have a CD45R0⁺CD62L⁺CCR7⁺ surface phenotype and survey the peripheral lymphoid tissues for specific antigen. A second population of cells, called *effector memory T cells*, have a CD45R0⁺CD62L[−] surface phenotype and express a variety of chemokine receptors

other than CCR7 and survey the nonlymphoid tissues for specific antigen. The extent to which effector memory cells are derived from central memory cells or directly differentiate from T_h1 cells remains unclear. Both central and effector memory T cells recirculate, with substantial numbers of both cell subsets found in the blood. A fourth memory cell population, T resident memory (Trm) cells, is found in nonlymphoid tissues, such as the skin and lung, and does not recirculate in the blood. On the basis of studies of the murine skin, Trm and central memory T cells appear to have a common clonal origin. Studies comparing the memory CD4 T cell responses of infants and young children with those of adults following primary CMV infection suggest that the infant/child responses are skewed toward central memory rather than effector memory responses, with an overall reduced production of T_h1 cytokines (Tu et al., 2004). Similarly, the pertussis antigen-specific CD4 T-cell response of infants following the receipt of a Diphtheria, Tetanus, acellular Pertussis [DTaP] and tetanus toxoid, reduced diphtheria toxoid, acellular pertussis [Tdap] (DTaP) vaccination series appears to be skewed toward central memory cells and limited IFN- γ production compared with that of Tdap-vaccinated adults (Sharma and Pichichero, 2012). Relative blunting of T_h1 memory cell responses in older infants and children likely also applies to the young infant and may contribute to the vulnerability of human infants to severe and disseminated primary tuberculosis (Vanden Driessche et al., 2013).

Regulatory T Cells

Treg cells have a CD25^{high}CD127^{low} surface phenotype and are a distinct subset of CD4 T helper cells critical for maintenance of immune self-tolerance and homeostasis by suppressing aberrant or excessive immune responses harmful to the host (Ohkura et al., 2013). Treg cells are defined by having an immune-suppressive phenotype with high, sustained expression of the transcription factor FOXP3 and a number of other Treg cell signature genes (Sakaguchi et al., 2013). Mutations in the *FOXP3* gene can result in an inherited multisystem autoimmune disease characterized clinically by diarrhea, insulin-dependent diabetes mellitus, thyroid disorders, and eczema, called *X-linked neonatal diabetes mellitus, enteropathy, and endocrinopathy syndrome* (Wildin et al., 2001).

Natural (thymic) Treg cells develop as a distinct lineage in the thymus, while induced (peripheral) Treg cells arise in the periphery from conventional CD4 T cells in the presence of TGF- β , retinoic acid, and microbial antigens and metabolites, such as short chain fatty acids (Tanoue et al., 2016). Naïve CD4 T cells of the second-trimester fetus are skewed toward differentiation into peripheral Treg cells rather than effector cells compared with adult naïve CD4 T cells. Murine SCID/human chimera experiments suggest that this skewing is a feature of naïve CD4 T cells that arise from fetal HSCs rather than adult HSCs (Mold et al., 2010). It is not known when in ontogeny hematopoiesis switches from the fetal-type HSC to the adult type, raising the possibility that at least some neonatal and infant T cells could be fetal HSC derivatives and, as a result, have distinct immune function. Defects in Treg cell function and number have been described in a series of different autoimmune diseases, including type 1 diabetes, systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis, and inflammatory bowel disease. Clinical trials using the transfer of ex vivo expanded Treg cells for treatment of type 1 diabetes, graft-versus-host disease, and other immune-mediated diseases are under way (Bluestone et al., 2015).

Relevant to the interpretation of animal models for neonatal immunology, ontogeny of FoxP3-expressing Treg cells is much

more advanced in humans than in mice (Fontenot et al., 2005). FoxP3⁺ Treg cells are almost completely lacking in neonatal mice, while they are abundant in the thymus and mesenteric lymph nodes in the human fetus as early as 20 weeks' gestation (Michaels et al., 2006). It appears that maternal cells cross the placenta to reside in fetal lymph nodes, inducing the development of fetal Treg cells suppressing immunity against maternal antigens and probably also playing a role in immune homeostasis after birth (Mold et al., 2008). Therefore it does not seem surprising that Treg cells can be detected in neonatal tissues as early as 23 weeks' gestation (Weitkamp et al., 2009). Consistent with the increased concentration of Treg cells in fetal tissues between 12 and 20 weeks' gestation, UCB from preterm infants born between 24 and 31 weeks' gestation contains a higher percentage of Treg cells compared with that of term infants (Dirix et al., 2013). This imbalance persists until later childhood and may play a role in the immune challenges former preterm infants face. In general, the critical maturation events in the developing immune system that underlie the high vulnerability to both infection and inflammation in the (preterm) neonate remain largely understudied (Sharma et al., 2012).

$\gamma\delta$ T Cells

About 2%–5% of T-lineage cells of the thymus and peripheral blood express $\gamma\delta$ TCR. Despite the potential for a highly diverse $\gamma\delta$ TCR repertoire, $\gamma\delta$ TCR use is highly restricted in terms of variable (V) segment use, with V γ 9V δ 2 T cells being the predominant $\gamma\delta$ T-cell subset in adult peripheral blood. Gamma-delta T cells, which can be more innate-like or more adaptive-like in their immune function depending on the context (Vermijlen and Prinz, 2014), can produce T_h1- and T_h17-type cytokines, kill virally infected or tumor target cells by cell-mediated cytotoxicity, and functionally interact with other cell types of the immune system, such as B cells and NK cells. V γ 9V δ 2⁺ T cells are innate-like in their immune function in that they are not activated by their TCR-recognizing MHC/peptides but rather utilize other receptors, such as the butyrophilin subfamily 3 member A1 (BTN3A1), to recognize microbe- and host-derived phosphorylated prenol metabolites (collectively referred to as *phosphoantigens*) (Vermijlen and Prinz, 2014). Older work suggested that this V γ 9V δ 2 T-cell predominance was due to postnatal expansion in response to exposure to bacterial-derived phosphoantigens. However, studies of the human fetus suggest otherwise in that V γ 9V δ 2 T cells are also the predominant $\gamma\delta$ T-cell subset in fetal blood and, like their adult counterparts, are programmed to rapidly respond to phosphoantigens with IFN- γ and cytotoxin release (Dimova et al., 2015). These findings suggest that endogenous phosphorylated prenol metabolites are sufficient for such immune programming of $\gamma\delta$ T cells in the fetus. An example of a more adaptive-like $\gamma\delta$ T-cell response is illustrated by V γ 8V δ 1⁺ T cells, which were first identified in fetuses with congenital CMV infection (Vermijlen et al., 2010). These V γ 8V δ 1⁺ T cells have the ability to lyse CMV-infected target cells in a TCR-dependent manner and have the potential to serve as non-MHC-restricted antiviral adoptive immunotherapy (e.g., in the post-HSC transplant setting) (Deniger et al., 2014).

Natural Killer T Cells

NKT cells are so named because they express $\alpha\beta$ TCRs in conjunction with CD161 (NKR-P1A), the human orthologue of the mouse NK1.1 protein, and other NK-cell markers, including CD56, CD57, and NKG2D. Unlike conventional $\alpha\beta$ T cells, NKT cells that emigrate from the thymus into the periphery have a uniformly

CD45R0⁺ surface phenotype and the ability to rapidly secrete high levels of T_H1 and T_H2 cytokines and to carry out cell-mediated cytotoxicity. Human NKT cells have a highly restricted repertoire of $\alpha\beta$ TCR (TCR α chains containing the V α 24J α 18 segments in association with TCR β chains containing V β 11 segments) and are positively selected during thymocyte development by the nonclassical MHC molecule CD1d rather than by MHC class I or class II molecules. The invariant TCR of NKT cells can recognize endogenously produced β -linked glycolipids, such as β -galactosylceramide, bound to CD1d, which may serve as a microbial-induced danger signal (Brennan et al., 2011). The role of the invariant $\alpha\beta$ TCR in NKT-cell immunity remains controversial, and it has been proposed that activation of these cells by cytokines, such as IL-12, may be more important for their mediating an innate-like immune response (Brigl et al., 2011). NKG2D-dependent but TCR-independent activation of NKT cells (e.g., for cytotoxic activity) can also occur. NKT cells with invariant TCR can be divided into a CD4⁺(CD8⁻) subset that expresses CD62L and may be involved in recirculation in secondary lymphoid tissues and a CD4⁻CD8⁻ cell subset that may mainly serve as effector cells at sites of extralymphoid tissue inflammation. In addition to their potential role in antimicrobial host defense, NKT cells have also been implicated as negative regulators of certain T-cell-mediated immunopathologic responses, as relative deficiency of their numbers has been associated with certain autoimmune diseases, graft-versus-host disease following hematopoietic cell transplant, and asthma.

NKT-lineage cells are present in the human fetal thymus by the beginning of the second trimester of gestation, and their relative frequencies compared with those of the other thymocyte subsets decline with increasing gestational age because of the rapid expansion of thymocytes differentiating by the conventional positive selection. Fetal and postnatal thymic NKT cells, which are largely CD4⁺CD45R0⁺, express high levels of IL-7 receptors, and their development appears to be largely IL-7 dependent. Extrathymic fetal NKT-cell populations are found in the small intestine, where they may constitute up to 5% of all T cells in this tissue, and in the lung, spleen, and mesenteric lymph nodes (Loh et al., 2014). Those NKT cells found in the fetal small intestine are distinct from those of fetal peripheral lymphoid tissue in having greater capacity to produce IFN- γ and lower levels of expression of CD62L. Murine studies suggest that commensal bacteria may be an important source for NKT-cell expansion and maturation, but the finding of a human NKT-cell population with mature features in the fetal intestine before bacterial colonization of the gut suggests a different mechanism, such as the presentation of endogenous glycolipids by CD1d, which is abundantly expressed in the fetal intestine. Circulating NKT cells in the neonate, infant, and young child constitute approximately 0.06% of circulating lymphocytes, a frequency that is only modestly lower than the mean of 0.2% for adult peripheral blood (Berzins et al., 2005). At all ages there is striking individual variation in values, with frequencies ranging from less than 0.001% to more than 0.5% of circulating lymphocytes.

Mucosal-Associated Invariant T Cells

MAIT cells are a population of CD8⁺ or CD8⁻CD4⁻ $\alpha\beta$ T cells that predominantly express an invariant V α 7.2 and J α 33 TCR α chain. They are positively selected during thymic development by MR1, an MHC class I-like protein that is widely expressed on hematopoietic and epithelial cells. Antigen for the MAIT cell $\alpha\beta$ TCR consists of bacterial- or fungal-derived metabolites of the

riboflavin biosynthetic pathway that bind to MR1 at a site analogous to the peptide-binding groove used by conventional MHC class I heavy chains (Birkinshaw et al., 2014). MAIT cells have the ability to produce T_H1 and T_H17 cytokines in response to polyclonal stimuli, including treatment with IL-12 or IL-18, and can also kill bacterially infected epithelial cells by cell-mediated cytotoxicity. MAIT cells constitute up to 10% of circulating $\alpha\beta$ T cells of healthy adults and uniformly have a memory (CD45RA⁻CD45R0⁺) cell surface phenotype. MAIT cells are the predominant $\alpha\beta$ T-cell type in the liver and the lamina propria of the healthy intestine (Dusseaux et al., 2011) and are also found in lung tissue. Murine studies have shown that MAIT cells can mediate protection against a variety of bacterial pathogens, including mycobacteria. Intrathymic MAIT cell precursors, which are CD161^{high}V α 7.2⁺ but IL-18R^{low}, are detectable at 18 weeks' gestation. MAIT cells with an activated and proliferative phenotype (i.e., IL-18R^{high}CD45R0⁺Ki67⁺) are easily detected in the small intestine, liver, and lung between 18 and 23 weeks' gestation (Leeansyah et al., 2014). These fetal intestinal MAIT cells secrete IFN- γ and IL-22 in response to *E. coli* and anti-CD28 monoclonal antibody. Collectively, these findings suggest that although fetal MAIT cells develop in the absence of exposure to commensal microbes, they potentially could mediate host defense against intrauterine bacterial and fungal infection in the extralymphoid tissues. MAIT cells in the UCB of neonates, which constitute approximately 0.7% of circulating $\alpha\beta$ T cells, have a surface phenotype (e.g., CD45RA⁺) that suggests that they may be RTEs that are in transit to the extralymphoid tissues, where they may mature and acquire a memory phenotype, as apparently occurs in the fetus (Leeansyah et al., 2014).

B Lymphocytes

B cells are lymphocytes that express BCRs, which consist of surface Ig in association with Ig α and Ig β signaling molecules and the cytoplasmic Bruton tyrosine kinase (Btk) (Fig. 36.8). The engagement of the BCR by high-affinity antigen results in B-cell activation and clonal expansion and, in some instances, terminal B-cell differentiation into antibody-secreting plasma cells. Secreted antibodies form the humoral arm of the immune system and provide the main form of immune protection against many pathogens, particularly during the extracellular phases of their life cycle. Although the B-cell compartment is well formed before birth, full diversification of the antibody repertoire and the efficiency of somatic hypermutation, which generates higher affinity antibodies, is not achieved until late in infancy.

B-Cell Development

The early phase of B-cell development, like T-cell development, is antigen independent. The first B lineage-committed progenitors that have not undergone V(D)J recombination of the Ig genes (pro-B cells) express CD19, CD34, TdT, RAG1, and RAG2. These cells undergo heavy chain D to J gene segment rearrangements followed by V to DJ rearrangement. As in TCR gene rearrangement, TdT is used during this process to insert nucleotides between the segments to create additional junctional diversity at CDR3, which is encoded by the 3' end of the V segment and the D and J segments. CDR3 is an important determinant of antibody specificity as it forms the central portion of the antigen-binding site. If the Ig heavy chain gene rearrangement is productive, it is expressed on the cell surface in association with a surrogate light chain consisting of the V-preB and λ 5 polypeptides. Cells with a nonfunctional Ig heavy chain gene rearrangement or that express Ig heavy chain protein that assembles poorly with the surrogate light chain die by apoptosis.

• **Fig. 36.8 Human B-Cell Development.** A common lymphoid progenitor or lymphoid-primed multipotent progenitor (LMPP) cell gives rise to a pro-B cell that expresses surface CD19 and CD20 and that is committed to B-lineage-cell differentiation. The immunoglobulin (Ig) heavy chain gene locus undergoes V(D)J rearrangement, and, if productive, the B-lineage cell proceeds to the pre-B-cell stage, expressing a pre-B-cell receptor (pre-BCR). The pre-BCR consists of the Ig heavy chain in association with a surrogate light chain that consists of two polypeptides—V pre-B and λ 5—and the proteins Igα and Igβ that are required for receptor complex surface expression and signaling. The Ig light chains undergo rearrangement in the pre-B cell, and, if productive, the pre-B cell differentiates into a B cell that expresses a B-cell receptor (BCR) that contains a mature surface Ig molecule. *Btk*, Bruton tyrosine kinase.

• **Fig. 36.9 Structure of Monomeric Immunoglobulin.** (Modified from Mix E, Goertsches R, Zett UKL. Immunoglobulins: basic considerations. *J Neurol.* 2006;253:V9–V17.)

The pre-BCR signals use Btk (Fig. 36.9), which accounts for why in cases of genetic deficiency of Btk (X-linked agammaglobulinemia) there is a maturational arrest at the pre-B-cell stage. The next stage involves V_L to J_L gene rearrangement, and, if productive, the newly expressed Ig light chain replaces the surrogate light chain. The light chain can be derived from either the kappa chain (60% of B cells) or the lambda chain (40% of B cells) gene clusters. The completed BCR is antigen specific and contains a surface IgM molecule. B-lineage cells also express surface IgD with the same antigen specificity as IgM, which is generated by alternative exon usage in the constant region of the Ig heavy chain gene. B-cell development initially occurs in the fetal liver, with a switch to the bone marrow beginning in the second trimester of gestation.

B-Cell Preimmune Selection and Maturation

Immature B cells of the bone marrow that have successfully produced productive heavy and light chains express these as IgM on the cell surface. A large proportion of these BCRs are autoreactive (i.e., they bind with relatively high affinity to molecules on other cell types within the bone marrow microenvironment or peripheral lymphoid organs). An important immune tolerance mechanism is the testing of immature B-lineage cells of the bone marrow for self-reactivity. At this stage of B-cell development, BCR signaling as part of self-reactivity maintains RAG activity, allowing the B cell to undergo a secondary V-to-J light chain rearrangement, a process known as *receptor editing*. If this eliminates BCR autoreactivity and cell signaling, RAG activity ceases, and the B cell enters the circulation as a peripheral transitional B cell to complete its maturation. Otherwise, additional light chain rearrangement can occur. Most initially autoreactive immature B cells can be converted to nonautoreactivity by receptor editing, allowing most B cells with productive Ig heavy chain rearrangements to contribute to the final repertoire.

Persistently autoreactive B cells are probably eliminated either by a process of clonal deletion, which involves apoptosis induced by strong BCR signaling (Wardemann and Nussenzweig, 2007), or by anergy, in which the B cells are functionally inactivated. Anergic B cells have been identified as having an $IgD^+IgM^-CD27^-$ surface phenotype and constitute about 3% of peripheral blood B cells in adults. These anergic B cells have BCRs with autoreactive antigen specificity that mediate a decreased calcium flux and tyrosine phosphorylation after their engagement (Duty et al., 2009). Anergic B cells probably die over a period of days to weeks by apoptosis.

$IgM^{high}IgD^{high}$ transitional B cells can be identified in the bone marrow and circulation by their high levels of expression of CD5, CD10, CD24, and CD38 and low levels of adenosine triphosphate-binding cassette subfamily B member 1 (ABCB1) (Wirths and Lanzavecchia, 2005). Analogous to RTEs, these circulating transitional B cells undergo a post-bone marrow phase of peripheral maturation into fully mature naïve B cells that involves an increase in CD21 and ABCB1 expression and a decrease in CD5, CD10, CD24, and CD38 expression. The maturation of transitional B cells into fully mature antigenically naïve B cells includes negative selection of B cells with autoreactive BCRs that have entered the periphery and that have somehow escaped central tolerance mechanisms in the bone marrow (Samuels et al., 2005; Meffre, 2011). Although the mechanisms involved in this secondary checkpoint for B-cell tolerance remain poorly understood, they may involve, at least in part, the death of autoreactive B cells because of their greater dependence for survival on B-cell activating factor (BAFF), a member of the TNF ligand superfamily, than

nonautoreactive B cells. The transitional B-cell subset is also enriched in regulatory B cells, which have the capacity to express IL-10 after strong stimulation and, like Treg cells, may negatively regulate adaptive immune responses.

Most transitional B cells that escape negative selection become fully mature naïve $IgM^{high}IgD^{high}CD27^-ABCB1^+$ follicular B cells and enter follicle areas of the secondary lymphoid tissue by the interaction of their CXCR5 chemokine receptors with chemokines in the follicle (CXCL13). These cells can recirculate between the follicles of the peripheral lymphoid organs, including the spleen, lymph nodes, and Peyer patches, and the blood and lymph (Allen et al., 2007). Follicular B cells include most of those that are involved in adaptive immune responses to T-dependent antigens, such as proteins and protein-carbohydrate conjugates.

Fetal and Neonatal B-Cell Development and Surface Phenotype

B cells expressing surface IgM are present by 10 weeks' gestation. The frequency of B cells in the tissues rapidly increases, such that by 22 weeks' gestation the proportion of B cells in the spleen, blood, and bone marrow is similar to that of adults. The concentration of B cells in the circulation is higher during the second and third trimesters than at birth (Schultz et al., 2000). After birth the concentration of B cells increases to peak levels between 6 and 12 months of age, which is followed by a gradual decrease until stable adult values are reached.

Approximately 70%–75% of UCB B cells are of the transitional subset, whereas transitional B cells usually constitute 10% or less of adult peripheral blood B cells, and 25%–30% are fully naïve B cells (Wirths and Lanzavecchia, 2005; Avery et al., 2008). $CD27^+$ B cells, which include most memory B cells in adults, are at low levels or undetectable in UCB, consistent with the antigenic naïveté of the healthy newborn. Neonatal naïve B cells are functionally distinct from their adult counterparts, having significantly lower expression of the IL-4 receptor alpha chain and responsiveness to IL-4 as assessed by tyrosine phosphorylation of STAT6 (Tian et al., 2006). Circulating newborn B cells are deficient in the purine ectoenzyme CD73, impairing their capacity for extracellular purine salvage (Pettengill and Levy, 2016). Newborn naïve B cells demonstrate adult-level expression of TLRs and CD40, but responses to stimulation of these receptors are distinct, including (1) impaired neonatal TLR2- and TLR7-mediated as well as (CD40+ TLR)-mediated but enhanced TLR9-mediated cytokine production and (2) impaired CD40-mediated Ig secretion (Pettengill et al., 2016). With respect to the quantity of B cells, absolute B-cell numbers double in the first 6 months of life from those at birth, mainly due to expansion of fully mature naïve B cells and, to a lesser extent, transitional B cells.

B-Cell Activation, Somatic Hypermutation, and Isotype Switching

When mature naïve B cells contact antigen through the BCR, a signal is transduced that promotes further growth and differentiation into memory B cells and plasma cells. BCR signaling involves activation of the tyrosine kinases spleen tyrosine kinase (Syk) and Btk, which are also involved in pre-BCR signal transduction, which results in transcriptional regulation by Elk-1, c-Myc, NF- κ B, and NFAT (Corneth et al., 2016). The T-dependent B-cell response to protein antigens involves the internalization of protein bound to the BCR and its processing into peptides that are loaded onto MHC class II molecules. These peptide/MHC class II complexes that are expressed on the B-cell surface activate CD4 T cells via

their TCR, resulting a series of CD4 T cell/B-cell interactions, including between CD40L and CD40 receptor, between IL-21 and IL-21 receptor, between ICOS and ICOS ligand.

Both the B cells activated by protein antigen and the peptide antigen-specific CD4 T cells they activate and interact with enter the follicles of secondary lymphoid tissue, where these interactions continue. The activated B cells undergo massive clonal expansion and differentiation giving rise to histologically evident germinal centers. Most germinal center B cells undergo somatic hypermutation in which antigen combining site regions encoded by productively rearranged V, D, and J segments of the Ig heavy chain gene and the V and J segments of the light chain gene accumulate random point mutations that result in amino acid substitutions. Those B cells with genetic variants that increase the affinity of the BCR for antigen outcompete those having BCRs with unchanged or reduced affinity. This affinity maturation process dramatically increases the ability of antibody to perform effector function, such as neutralization or opsonization. Somatic hypermutation requires activation-induced cytidine deaminase expression by germinal center B cells as well as the action of error-prone DNA polymerases. The peak of somatic mutation is approximately 10 to 12 days after immunization with a protein antigen.

Human B cells produce five isotypes of antibody (i.e., IgM, IgD, IgG, IgA, and IgE). The IgG and IgA isotypes can be, respectively, divided into the IgA1 and IgA2 subclasses and the IgG1, IgG2, IgG3, and IgG4 subclasses. During their process of differentiation from naïve B cells into memory B cells or plasma cells, B cells are able to change from expressing IgM to expressing other antibody isotypes without changing antigen specificity. With the exception of IgD expression, which involves alternative messenger ribonucleic acid (RNA) splicing, this switching involves isotype recombination, the genetic replacement of the IgM-specific portion of the constant region (C_μ) of the heavy chain with a new isotype-specific gene segment (Fig. 36.10). As in V(D)J recombination, the intervening DNA is excised as a circle. Isotype recombination is mediated by switch regions that are positioned immediately upstream of each of the isotype-specific C regions (with the exception of IgD). Successive multiple isotype switching by a single B cell can also occur—for example, IgM to IgG and then, on reactivation by antigen, IgG to IgE. Cytokines secreted by T cells or other cell types play an important role in promoting or inhibiting switching to a specific isotype. For example, IL-4 or IL-13 is absolutely required for isotype switching to IgE, a process that can be inhibited by the presence of IFN- γ .

IgA, which is the predominant Ig isotype secreted into mucosal secretions, has a distinct CD4 T-cell-independent and CD40L-independent pathway for its generation by isotype switching that utilizes the TNF ligand superfamily—a proliferation-inducing ligand (APRIL) and BAFF. These cell surface proteins, which are expressed by a variety of cell types, including intestinal epithelium, may play an important role in the development of IgA-secreting plasma cells in the gut in response to commensal bacteria.

Neonatal Antibody Responses to T-Dependent and T-Independent Antigens

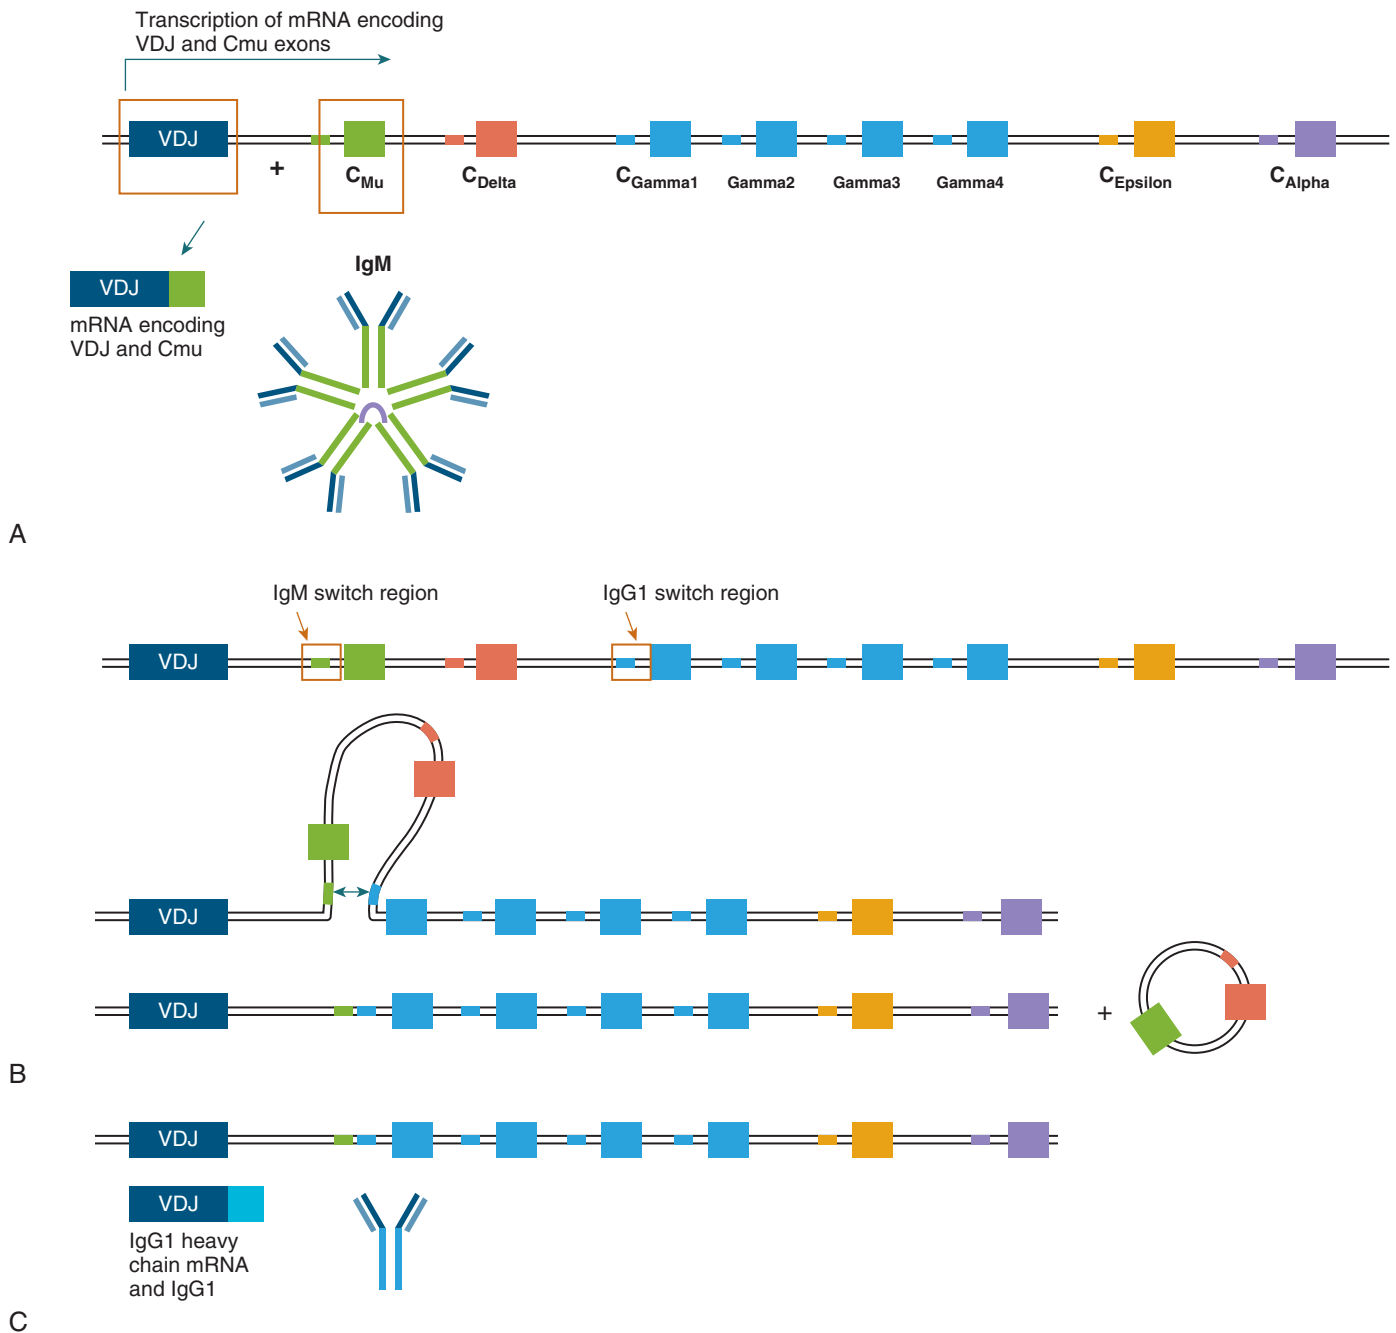

A study comparing the RSV F protein-specific heavy chain antibody responses in RSV-infected neonates and adults revealed a distinct usage of variable heavy chain segments in the neonates, suggesting that there are major age-related differences in the selection of antibody specificities. Importantly, there was also significantly less somatic hypermutation of the Ig heavy chain gene and decreased N-nucleotide addition in the antibody response of neonates

compared with adults (Williams et al., 2009). These differences would be expected to result in a relatively poor RSV-specific antibody response in the neonate and young infant. Similarly, restricted heavy chain variable gene usage and lack of somatic mutations were found in rotavirus-specific B cells of human infants (Weitkamp et al., 2003, 2005).

Whether isotype switching is limited in T-dependent responses in the neonate in response to infection is less clear. Although this is plausible, given that CD40L expression by activated neonatal CD4 T cells may be decreased (Durandy et al., 1995), studies are needed to determine if reductions in CD40L expression by antigen-specific T cells also occur in response to neonatal vaccination and, if so, whether such reduced expression correlates with an impairment of the other important roles of CD40L in promoting B-cell antibody responses (i.e., memory B-cell development and somatic hypermutation). An additional factor that may contribute to the modest reduction in T-dependent antibody production is the reduced expression on B cells (nearly all of which are naïve $\text{IgM}^+\text{IgD}^+\text{CD27}^-$ follicular B cells) from preterm neonates and, to a lesser degree, term neonates of the receptors for BAFF and APRIL (Kaur et al., 2007). Receptors for BAFF and APRIL help promote T-dependent B-cell differentiation into plasma cells, plasma cell survival, and T-independent isotype switching. Importantly, some antibody responses, such as the T-independent antibody response to bacterial capsular polysaccharides, such as those of *Streptococcus pneumoniae*, are not fully established until after 2 to 3 years of age (Mond and Kokai-Kun, 2008); the mechanisms for this delayed competency remain unclear.

Immunoglobulins

Igs, or antibodies, are a heterogeneous group of proteins that are detectable in plasma and body fluids and on the surfaces of mucosal barriers and B cells that bind specifically to antigens. The functions of Igs relevant to fetal and neonatal immunity are summarized in Table 36.2. There are five known classes of Igs: IgG, IgM, IgA, IgE, and IgD. Human IgM circulates as a pentamer or hexamer, and IgA circulates as a dimer. Multimers are formed in association with an additional J chain. The functions of individual Ig classes are different but overlapping (Table 36.2). The prototype Ig molecule consists of a pair of identical heavy chains that determine the Ig class in combination with a pair of identical light chains, which are linked by disulfide bonds (see Fig. 36.9). Each Ig molecule contains two N-terminal, identical domains with antigen-binding activity that are formed by the variable regions of a heavy chain and a light chain. The antigen-binding site is formed by three complementarity-determining regions: CDR1, CDR2, and CDR3, which are hypervariable in their amino acid sequences as a result of V(D)J recombination of the heavy and light chain genes and, in some instances, somatic hypermutation. The C-terminal region of the two heavy chains forms the Fc (fraction crystallizable) region, which is not involved in antigen binding but mediates Ig effector functions. The principal functions of the Fc region include receptor-mediated phagocytosis (IgG), antibody-dependent cellular cytotoxicity (IgG), release of inflammatory mediators from mast cells and basophils (IgE), receptor-mediated transport through mucosa (IgA and IgM) and placenta (IgG), and complement activation (IgG1, IgG2, IgG3, and IgM). The five different isotype classes of human Igs (IgG, IgM, IgA, IgD, and IgE) are defined structurally by differences in the heavy chain constant regions (CH)1 and CH2 domains of the Fc fragments. Within isotypes, there are four IgG subclasses (IgG1, IgG2, IgG3, and IgG4) and two IgA subclasses (IgA1 and IgA2).

(B) Recombination highlighting the immunoglobulin M (IgM) and the immunoglobulin G1 (IgG1) switch regions. (C) IgG1 heavy chain mRNA and protein.

Immunoglobulin G

IgG is the predominant Ig isotype at all ages (Stiehm and Fudenberg, 1966). In adults, IgG1 is the predominant subclass, accounting for approximately 70% of total IgG, and IgG2, IgG3, and IgG4 account for approximately 20%, 7%, and 3% of the total, respectively. Passively derived maternal IgG is the source of virtually all of the IgG subclasses detected in the fetus and neonate. Because the IgG plasma half-life is about 21 days, these maternally derived IgG levels fall rapidly after birth. The levels of IgG synthesized by the neonate and that are derived from the mother are approximately equal at 2 months of age, and by 10 to 12 months of age nearly all

of the IgG is infant derived. IgG values typically reach a nadir of approximately 400 mg/dL in term infants at 3 to 4 months of age and rise thereafter. Premature infants have lower IgG concentrations at birth that typically reach a nadir at 3 months of age; mean IgG values of 82 and 104 mg/dL are observed in infants born at 25 to 28 weeks' gestation and 29 to 32 weeks' gestation, respectively.

Immunoglobulin M

IgM is the only isotype besides IgG that binds and activates complement. IgM has a half-life in the blood of 5 days. The concentration of IgM in the blood increases from a mean of 6 mg/

TABLE 36.2 Characteristics and Functions of Immunoglobulins

| | Molecular Mass (kDa) | Serum Concentration (g/L) | Serum Half-Life (Days) | Neutralization | Opsonization | Complement Activation | Epithelial Transport | Placental Transport | Sensitization for Killing by Natural Killer Cells | Sensitization of Mast Cells and Basophils |

dL in infants born at less than 28 weeks' gestation to 11 mg/dL for those born at term (Avrech et al., 1994). This IgM is likely to be preimmune and not the result of a B-cell response to foreign antigens. Rather, it is likely enriched for polyreactive natural antibodies that may play an important role in innate defense against infection. Postnatal IgM concentrations rise rapidly for the first month and then more gradually, presumably in response to antigenic stimulation in both premature infants and term infants. By 1 year of age, the values are approximately 60% of those in adults. Because maternal–fetal transport of IgM does not occur, elevated (greater than 20 mg/dL) IgM concentrations in UCB suggest possible intrauterine infections, although many infants with congenital infections have normal values.

Immunoglobulin A

IgA does not cross the placenta, and its concentration in UCB is usually 0.1 to 5.0 mg/dL, approximately 0.5% of the levels in maternal sera (Avrech et al., 1994). The concentrations are similar in term and premature neonates (Cederqvist et al., 1978), and both IgA1 and IgA2 are present. IgA has a half-life of 6 days in blood. Secretory IgA can be detected in the saliva of neonates as early as 3 days after birth.

The concentrations of IgA in serum increase to 20% of adult levels by 1 year of age and rise progressively through adolescence. Increased UCB IgA concentrations are observed in some infants with congenital infection, such as toxoplasmosis, and are common in those infected with HIV by vertical transmission. The amount of IgA produced daily is estimated to exceed that of all Ig isotypes combined. The overall importance of IgA in host defenses is only partially understood, as individuals with complete IgA deficiency are typically asymptomatic. Recent studies suggest that mucosally secreted IgA may play an important role in regulating the composition of the human gut microbiome (Kurashima and Kiyono, 2017),

and that in cases of IgA deficiency, this role may be compensated for by mucosally secreted IgM.

Immunoglobulin E

Although IgE synthesis by the fetus is detectable as early as 11 weeks, the concentrations of IgE in UCB are typically low, with a mean of approximately 0.5% of maternal levels (Avrech et al., 1994). IgE concentrations are higher in infants born at 40 to 42 weeks' gestation than in those born at 37 to 39 weeks. The rate of postnatal increase differs and is greater in infants predisposed to allergic disease or greater environmental exposure to allergens (Edenharter et al., 1998). The concentration of IgE at birth appears to have limited predictive value for later development of atopic disease for most individuals. Maternofetal transfer of IgE appears to be a common cause of elevated IgE concentration at birth (Bonnelykke et al., 2010). On the basis of murine experiments, one potential mechanism for such transfer may be IgG anti-IgE complexes being transported via FcRn, which has substantial affinity only for IgG.

Immunoglobulin D

IgD is detectable in serum from the UCB of term and premature infants, with mean levels of approximately 0.05 mg/dL (Avrech et al., 1994). These levels increase during the first year of life. The role of IgD in normal humoral immunity remains unclear. Elevated levels of IgD are associated with certain monogenic autoinflammatory disorders, such as mevalonate kinase deficiency and familial Mediterranean fever.

Polyclonal Immunoglobulin Therapy for Prevention or Treatment of Bacterial Infections

Intravenous Ig (IVIG) has been extensively evaluated for the prevention of nosocomial or late-onset pyogenic infections in premature

neonates. A 2013 Cochrane analysis identified 19 randomized controlled trials in which IVIG was used for the prevention of sepsis in the setting of neonatal intensive care units. These trials included a total of approximately 5000 infants born at less than 37 weeks' gestation or with a birth weight of less than 2500 g (Ohlsson and Lacy, 2013). When combined, these studies showed significant reductions in both sepsis and in one or more episodes of any serious infection. However, there were no significant decreases in the IVIG-treated infants compared with those who received placebo for overall mortality, the incidence of NEC, bronchopulmonary dysplasia, intraventricular hemorrhage, or the length of hospital stay. This and another analysis both concluded that IVIG is not indicated for prophylaxis in preterm neonates and neonates with low birth weight because there is no effect on long-term outcome and little or no effect on short-term outcomes.

Similarly, IVIG has been studied as a potential therapeutic in neonates with suspected or proven sepsis. A comprehensive randomized and controlled International Immunotherapy Study (INIS) trial investigating the use of IVIG as adjunctive therapy for suspected or proven serious neonatal infections involved 3493 infants enrolled in 113 hospitals in nine countries (INIS Collaborative Group, 2011). No significant differences in the primary outcome variable—death or major disability at the age of 2 years—was observed between IVIG-treated infants and those who received placebo. There were also no significant differences between the two groups in the incidence of subsequent sepsis episodes or the rates of major or minor disability at 2 years of age. A Cochrane analysis that included the results of the INIS report as well as seven additional randomized or quasi-randomized studies also failed to find a significant impact of IVIG therapy, including that enriched in IgM, in reducing death or major disability at 2 years of corrected age or in length of hospital stay (Ohlsson and Lacy, 2015). A single-center study published after the Cochrane analysis that used historical controls found that IgM-enriched IVIG significantly reduced early mortality in very low-birth weight infants; however, it did not reduce overall mortality or the incidence of intraventricular hemorrhage, periventricular leukomalacia, NEC, or bronchopulmonary dysplasia at discharge (Capasso et al., 2013). On the basis of these results and analyses, adjunctive therapy with IVIG, including the IgM-enriched form, is not recommended in the management of neonatal sepsis.

Monoclonal Antibody Prophylaxis to Prevent Infection

Monoclonal antibodies that are fully human derived or that were originally generated in another species, usually the mouse, and then humanized (i.e., by replacement of murine constant regions of the Ig chains with those of humans) are commonly used to treat human autoimmune diseases and cancer. Palivizumab, a monoclonal antibody against RSV, is licensed for the prevention of infection in the United States and recommended for infants at high risk of severe RSV disease. This includes infants born at less than 32 weeks' gestation or with chronic lung disease of prematurity or hemodynamically significant congenital heart disease. Such infants should receive up to five monthly doses during seasons of the year when RSV is prevalent.

Specific Immunologic Deficiencies of the Newborn and Their Diagnosis

The most common reason for increased immunologic susceptibility to infection in newborns, besides prematurity, is iatrogenic

immunosuppression caused by administration of corticosteroids for treatment or prevention of bronchopulmonary dysplasia. Such therapy is particularly associated with an increased risk of fungal infection, such as candidemia, particularly in the setting of indwelling intravascular catheters used for total parenteral nutrition.

Although less common than therapeutically induced immunodeficiency, genetically inherited primary immunodeficiencies (PIDs) can present in the neonatal period and may require prompt intervention for optimal outcome. There are approximately 300 recognized PIDs (Chinen et al., 2016), most of which are monogenic disorders (Boisson et al., 2015). The physician should attempt to differentiate infants with specific genetically regulated immunologic deficiencies from those with developmentally regulated, environmentally induced, or infection-related susceptibility to microbial invasion (Stiehm et al., 2015). Documenting a full family history during a prenatal visit, including whether there is consanguinity or the family is of an ethnicity that is known to have a high incidence of a particular PID (e.g., those of Athabascan Indian heritage and SCID caused by Artemis deficiency), can be helpful in identifying families who may have a PID. However, the lack of such history does not exclude PID, as a patient can have de novo mutations causing PID. These de novo mutations are not present in either the biological mother or father or siblings and are the result of a mutation in the egg of the mother or sperm of the father, or in rare instances in the fertilized egg itself. Such de novo mutations are increasingly recognized as result of whole-exome sequencing of the biological mother, biological father, and affected child trios (Ghaoui et al., 2015). What follows is a discussion of specific PIDs that may present in the newborn period and are important to recognize promptly.

Severe Combined Immunodeficiency

SCID is a rare category of diseases that severely impacts the development and/or function of both T cells and B cells. Most forms of SCID lack peripheral T cells (i.e., are T cell negative) and are due to thymic hypoplasia and markedly impaired production of new naïve CD4 and CD8 T cells. T cell–negative SCID can be divided into four major groups on the basis of whether peripheral numbers of B cells and/or NK cells are also reduced or absent (i.e., T[−]B[−]NK[−], T[−]B[−]NK⁺, T[−]B⁺NK[−], and T[−]B[−]NK⁺) (Chinn and Shearer, 2015).

T[−]B[−]NK[−] SCID accounts for more than half of all SCID patients, most of whom are males with the X-linked form that is due to deleterious mutations of the *IL2RG* gene, which encodes the common gamma chain (γ c or CD132). This chain is a shared component of the cytokine receptors IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Defects in the γ c protein abrogate the development of T cells in the thymus because of the lack of IL-7 receptor function and of NK cells in the bone marrow because of the lack of IL-15 receptor function. Although B cells in X-linked SCID develop normally, they are not able to mediate T-dependent antibody responses because they do not receive CD4 T-cell help and also because they lack functional IL-21 receptors. The less common autosomal recessive form of T[−]B[−]NK[−] SCID is primarily due to biallelic mutations in Janus-associated tyrosine kinase 3 (JAK3). This kinase is expressed in cells of hematopoietic lineage and associates with γ c as part of the cytokine receptor signaling cascade and is also the target of small-molecule drugs used for immunosuppression (Pesu et al., 2005). JAK3-deficient patients are clinically similar to those with γ c deficiency except that females and males are equally involved.

Patients with autosomal recessive T⁺B⁺NK⁺ SCID most commonly have biallelic mutations of the gene encoding the IL-7 receptor alpha chain (CD127) or, less frequently, of genes encoding the proteins CD3 δ (CD3D), CD3 ϵ (CD3E), CD3 ζ (CD247), CD45 (PTPRC), or coronin 1A (CORO1A). SCID caused by coronin 1A deficiency is distinct from the other forms in having a block in the release of fully mature thymocytes into the periphery but otherwise normal intrathymic T-cell development and a normal thymic shadow with radiologic imaging.

Patients with T⁺B⁺NK⁺ SCID have biallelic mutations of genes that encode proteins that are required for TCR and Ig gene rearrangement by V(D)J recombination, including RAG1, RAG2, Artemis, protein kinase catalytic subunit (PKCS), and XLF (Cernunnos) (de Villartay, 2015). These mutations prevent the formation of pre-TCRs on thymocytes and pre-BCRs on immature B cells, resulting in early T-cell and B-cell maturational arrest and an absence of peripheral T cells and B cells.

The T⁺B⁺NK⁺ SCID phenotype is due to biallelic mutations in genes encoding the enzymes adenosine deaminase (ADA) and adenylylase kinase 2 (AK2). Patients who lack ADA, an enzyme in the purine salvage pathway, accumulate deoxyadenosine triphosphate in red blood cells and lymphocytes, and the concentration correlates with disease severity. The ADA substrates, adenosine and deoxyadenosine, are found at increased levels in the serum. Developing thymocytes are particularly sensitive to these metabolic effects. ADA deficiency may also result in neonatal hepatitis, renal dysfunction, bone abnormalities (including flaring of the costochondral junction as seen on the lateral chest radiograph [termed *rachitic rosary*]) and pelvic dysplasia), sensorineural hearing impairment, and cognitive impairment. Patients with AK2 deficiency, which is also known as *reticular dysgenesis*, have severe neutropenia and also sensorineural hearing impairment.

A T⁺ SCID-like phenotype with severe immunodeficiency and opportunistic infections can also result in cases in which the production of T cells by the thymus is normal or modestly impaired but the peripheral T cells have severe functional defects. These defects can either be T-cell intrinsic, such as biallelic mutations of the genes encoding caspase recruitment domain family member 11, CD3 γ , ZAP-70, or the calcium channel proteins Stim1 and Orai1, or that are T-cell extrinsic and are due to a lack of MHC class II-restricted antigen presentation. MHC class II deficiency is due to biallelic mutations of the regulatory factor X family member genes *RFXANK*, *RFXAP*, and *RFX5*, or of *CIITA*, which all encode proteins that positively regulate the transcription of the MHC class II genetic loci (Hanna and Etzioni, 2014). An SCID-like clinical presentation with severe T-cell lymphopenia may occur for some causes of T-cell immunodeficiencies that can also present with a less severe phenotype and retention of greater numbers of T cells, such as cartilage hair hypoplasia syndrome, *Coloboma*, *Heart defects*, *choanal Atresia*, *growth Retardation*, *Genital abnormalities*, and *Ear abnormalities* (CHARGE) syndrome, or tetratricopeptide repeat domain 7 deficiency. Finally, mutations of genes that cause SCID that are hypomorphic (i.e., preserve some degree of normal protein function) can result in atypical forms in which the T-cell numbers may range from being only moderately depressed to normal values (e.g., certain missense mutations of the *IL2RG* gene in X-linked SCID).

T⁺ SCID can also occur in Omenn syndrome, which often presents in the neonatal period with diarrhea, intense erythroderma, alopecia, hepatosplenomegaly, and lymphadenopathy. Omenn syndrome was first described in cases of biallelic hypomorphic missense mutations of the *RAG1* gene or the *RAG2* gene but has

also been reported in cases of SCID caused by *IL2RG*, *LIG4*, *IL7R*, *ADA*, *DCLRE1C*, *AK2*, *RMRP*, *ZAP70*, *CHD7*, or *CARD11* mutations. Regardless of the genetic cause, the hematologic and immune phenotype is characteristic, with markedly increased eosinophilia, highly elevated serum levels of IgE, increased numbers of CD4 T cells, and markedly reduced numbers of CD8 T cells. Unlike CD4 T cells in healthy newborns, the CD4 T cells of Omenn syndrome are uniformly CD45R0⁺ and lack CD45RA expression.

T⁺ SCID can also be the result of the engraftment of maternal T cells into the fetus. The clinical consequences of maternal engraftment can range from asymptomatic to a mild erythematous rash to full-blown symptoms of graft-versus-host disease (e.g., severe dermatitis, gastroenteritis, hepatitis, and lung disease). Maternal T-cell engraftment can also result in hemophagocytic syndrome, which can lead to secondary changes in the numbers of other cell types, such as B cells, that can obscure the SCID diagnosis. Clues to maternal engraftment include the uniform expression of CD45R0 by the circulating T cells, and unusual CD4 T cell to CD8 T cell ratios. Maternal engraftment can be readily diagnosed by means of T-cell chimerism assays, such as the polymerase chain reaction (PCR)-based short tandem repeats/variable number tandem repeats (STR/VNTR) system (Khan et al., 2004).

Most infants with SCID appear healthy at birth. In the neonatal period a morbilliform rash, probably the result of attenuated graft-versus-host disease from transplacental passage of maternal lymphocytes, may be the only symptom of SCID. During the first several months of life, as acquired maternal antibody levels drop, failure to thrive and undue susceptibility to infection become universal features. Intractable diarrhea, pneumonia, and persistent thrush, especially oral thrush, constitute the triad of findings most frequently seen in infants with this disease. A diffuse pneumonia with severe hypoxemia due to *Pneumocystis jirovecii* is a classic presentation of SCID and usually occurs between 3 and 6 months of age although it rarely may occur in the neonatal period. Patients with SCID who receive live rotavirus vaccine, which is routinely first administered at 2 months of age, often develop persistent shedding and disease (Patel et al., 2010), and such symptoms should raise the suspicion of SCID or other severe T-cell immunodeficiency.

The diagnosis of SCID is often suggested by an opportunistic or unusually severe infection in the setting of profound lymphopenia (<1000 lymphocytes per microliter). Only 10% of patients with SCID have lymphocyte counts in the normal range, and the possible reasons for T⁺ SCID have been discussed previously. The thymus gland is not seen on chest radiographs except in some cases of T⁺ SCID or SCID because of defects in thymocyte egress, such as coronin 1A deficiency. Flow-cytometric analysis of T-cell, B-cell, and NK-cell populations, including the enumeration of CD4 and CD8 T cells and their naïve (CD45RA) and memory (CD45R0) subsets, is the most important confirmatory test. Other useful tests include measurements of ADA and purine nucleoside phosphorylase activity in red blood cells. Quantitative Ig levels are not particularly helpful in the diagnosis of neonatal SCID, because most IgG is maternal in origin, and IgA and IgM levels are often low in the neonatal period. Once the immunophenotype has been established, a precise molecular diagnosis should be obtained, and genetic counseling should be provided.

An effective strategy for detecting newborns with SCID with statewide newborn screening is now in place in more than 46 states of the United States. The test is based on the real-time PCR detection of sjTRECs, which are generated during V(D)J recombination of the TCR α/δ gene locus (see Fig. 36.7). Neonatal screening

involves extraction of total DNA from standard dried blood spots on filter paper that are obtained by heel stick in the nursery and used for other routine newborn screening tests. The turnaround time of the test is usually about 3 weeks. Abnormally low values of sjTRECs should lead to prompt flow-cytometric evaluation of lymphocyte populations as described previously.

SCID is a pediatric emergency, and is invariably fatal if untreated. Most untreated patients die in the first year of life. Treatment of SCID begins with aggressive antibiotic and antiviral therapy for infections, intravenous Ig replacement, and antibiotic prophylaxis for *Pneumocystis jirovecii* and environmental mycobacterial infections. Besides greater susceptibility to opportunistic infections, these infants are also susceptible to development of graft-versus-host disease, either before birth as a result of engraftment of maternal T lymphocytes or after birth as a result of the engraftment of T lymphocytes present in transfused blood products. Therefore infants in whom SCID is suspected should receive only irradiated CMV-negative blood products and should not be given live viral vaccines.

SCID treatment usually requires allogeneic HSC transplant, ideally from an HLA-matched sibling (Slatter and Gennerly, 2013). In one approach, conditioning regimens, such as busulfan, are not used and recipients usually become chimeric, with only T and NK cells of donor origin. B-cell function is frequently deficient, and many patients continue to require Ig replacement therapy. As there is not replacement of totipotent HSCs of the recipient with those of the donor, there is eventually a drop-off in T-cell numbers, requiring that the patients receive a “boost” transplant from the original donor (Heimall et al., 2017). An alternative approach is to use standard conditioning regimens that result in the replacement of all hematopoietic cell types of the recipient with those of the donor, including HSCs. This approach has an increased risk of complications in the early posttransplant period but avoids the need for later transplants and often leads to normal B-cell function, obviating the need for potentially lifetime Ig replacement therapy. ADA deficiency can be treated with enzyme replacement. This treatment involves weekly injections of ADA coupled to polyethylene glycol. Response, consisting of decreasing deoxyadenosine triphosphate levels and increasing T-cell numbers, is seen in most patients within weeks. Finally, retroviral lentiviral gene therapy based on vector-mediated transfer of a therapeutic gene into autologous HSCs has been used to treat patients with ADA and X-linked SCID and is under development for other disorders (Thrasher and Williams, 2017). Early problems in the treatment of X-linked SCID from insertional mutagenesis leading to endogenous gene dysregulation and leukemia have been avoided with currently used lentiviral vectors. The treatment of ADA SCID by gene therapy has not encountered any major safety issues.

DiGeorge Syndrome

The embryologic anlage of the thymus, parathyroid, and a portion of the great vessels is the endodermal epithelium of the third and fourth pharyngeal pouches (McDonald-McGinn et al., 2015). When normal development of these structures is disturbed, thymic and parathyroid hypoplasia and congenital heart disease involving the great vessels can occur. Infants with this disorder, DiGeorge syndrome, can exhibit abnormalities of calcium homeostasis during the neonatal period (hypocalcemia and tetany) and variable T-cell deficits, which is usually subclinical and only severe in about 1% of cases. Often, the syndrome is suspected because of congenital conotruncal cardiac defects (about 60% of cases), low-set ears, midline facial clefts, hypomandibular abnormalities,

and hypertelorism. The cardiac anomalies associated with 22q11.2 deletion syndrome are variable but usually involve the outflow tract and the derivatives of the branchial arch arteries. These defects include interrupted aortic arch type B, truncus arteriosus, and tetralogy of Fallot. Children with 22q11.2 deletion syndrome also exhibit a higher incidence of receptive-expressive language difficulties, cognitive impairment, and behavioral problems, including psychotic illness (Jolin et al., 2009; Papangelis and Scambler, 2013).

About 95% of patients with DiGeorge syndrome have a hemizygous interstitial three-megabase deletion of the 22q11.2 chromosomal region, which is flanked by two low copy repeat regions (McDonald-McGinn et al., 2015) and which is readily diagnosed by fluorescence in situ hybridization. This deletion results in hemizygosity for 46 protein-encoding genes, including *TBX1*, 7 microRNAs, and 10 long noncoding RNAs. Cases of DiGeorge syndrome lacking the 22q11.2 deletion should be evaluated for *TBX1* loss-of-function mutations, which can result in most of the features of DiGeorge syndrome, including T-cell immunodeficiency, hypoparathyroidism, and/or conotruncal cardiac lesions (Ogata et al., 2014). Clinical features suggestive of DiGeorge syndrome can also be observed in individuals with *CHD7* mutations, the cause of CHARGE syndrome, and in some cases of gestational diabetes, fetal exposure to retinoic acid, and other chromosomal deletion disorders.

In the nursery, identification of infants with congenital conotruncal abnormalities or unexplained persistent hypocalcemia should prompt consideration of this syndrome. In most cases the T-cell deficiency is not severe, with decreases in circulating CD4 T-cell and CD8 T-cell numbers to levels that are 25%–50% of those normal for age. However, in about 1 in 400,000 deliveries, infants with features of DiGeorge syndrome may have severe T-cell lymphopenia—that is, circulating naïve ($CD45^{RA+}CD62L^{+}$) T-cell numbers less than 50 per microliter. Severe T-cell lymphopenia in association with hypoparathyroidism and conotruncal congenital heart disease is called *complete DiGeorge syndrome* and is due to the 22q11.2 deletion in about 50% of cases, CHARGE syndrome in about 25% of cases, and gestational diabetes in about 15% of cases (Markert et al., 2009). Like SCID, complete DiGeorge syndrome is a medical emergency that prompts antibiotic prophylaxis for *Pneumocystis jirovecii* and nontuberculous mycobacteria, Ig replacement therapy, and protective isolation. All patients should also be evaluated for their CMV infection status, and, if positive, antiviral therapy should be started. Patients who are not infected with CMV should not be breastfed if their mother is CMV IgG antibody positive. About 30% of complete DiGeorge syndrome patients develop an extensive erythematous rash sometimes accompanied by gastrointestinal symptoms and hepatitis, which is referred to as *atypical complete DiGeorge syndrome*. These patients often have increased levels of circulating T cells in their blood that express memory markers, such as CD45RO, with similar T cells found in skin biopsy. These T cells, which are produced by the patient and are not the result of maternal engraftment, are oligoclonal in their TCR usage and do not provide useful immune function. Patients harboring these autoreactive T cells have been treated with immunosuppressive drugs, such as calcineurin inhibitors and glucocorticoids.

The only definitive therapy for complete DiGeorge syndrome is transplant of thymic epithelial tissue, which is derived from thymus tissue removed from otherwise healthy children as part of surgery for congenital heart disease (Markert et al., 2010). Small pieces of thymic epithelia are placed within the quadriceps muscle, and the de novo production of CD4 and CD8 T cells begins approximately 4 to 6 months after transplant. The transplant is

successful in about 80% of cases, so that antibiotic prophylaxis, Ig replacement therapy, and protective isolation can be discontinued, whereas live vaccination should continue to be avoided.

Combined Immune Disorders Involving T Cells and B Cells

Many monogenic immune disorders have complex phenotypes that involve both T and B cells in which the residual T-cell function is sufficient to result in a delayed presentation after the neonatal period. For example, Wiskott–Aldrich syndrome (WAS) is a combined immune disorder involving T cells, B cells, and APCs (Chandra et al., 2016). WAS affects males and is due to mutations of a gene located on the X chromosome that encodes WAS protein (WASp), an intracellular protein. WASp is expressed in all hematopoietic cells that interact with actin cytoskeleton and can also participate in transcriptional regulation. WAS is characterized by eczema (usually severe), thrombocytopenia, increased risk of malignancy, and susceptibility to recurrent sinopulmonary infections, severe herpesvirus infection, and, less commonly, classic opportunistic infections, such as infection with *Pneumocystis jirovecii*. Other manifestations that may be present in the newborn period include petechiae and bruises, bloody diarrhea, and hemorrhage after procedures. In infants with any of these clinical findings, thrombocytopenia in a complete blood count report is an important clue to possible WAS. In contrast to immune thrombocytopenia purpura, WAS platelets have a low mean platelet volume, and this finding is pathognomonic of the disorder. Characteristic immunologic findings include moderately decreased numbers of T cells, particularly those of the CD8 subset, with relatively subtle defects in T-cell proliferation, decreased IgM levels, and increased IgA and IgE levels. Many of these immunologic findings may not be evident in the neonatal period. Flow cytometry can be used to evaluate leukocyte WASp expression to make a provisional diagnosis of WAS. As for children with SCID, all blood products given to children with WAS should be CMV negative and irradiated before administration to avoid T-cell engraftment and graft-versus-host disease. WAS can be cured by HSC transplant, with the best results obtained with transplant before 3 years of age. Lentiviral gene therapy is a promising alternative for treatment (Thrasher and Williams, 2017).

B-Cell Immunodeficiencies

Most genetic defects that target B-cell immunity but leave T-cell immunity intact, such as X-linked agammaglobulinemia (XLA), are not detected in the neonatal period without special screening tests, such as flow cytometry to evaluate circulating B-cell numbers or intracellular expression of Btk by monocytes (Locke et al., 2014). Because of maternal transfer of IgG during the last trimester of pregnancy, infants with selective immunodeficiencies of B cells typically do not develop clinically significant hypogammaglobulinemia and recurrent or severe sinopulmonary infections with encapsulated organisms until after 3 to 6 months of age. Moreover, the absence of B cells from the circulation does not usually result in clinically detectable lymphopenia on the complete blood count. Analogous to screening for severe T-cell deficiency, neonatal screening for quantitative B-cell immunodeficiency is possible by assaying by PCR for kappa receptor excision circles (KRECs), which are stable circular DNA byproducts of V(D)J rearrangement of the kappa light chain Ig gene in B-lineage cells (Hammarstrom, 2014). Currently, KREC evaluation is not part of routine newborn screening in the United States.

Innate Immune Deficiency Disorders

Immune deficiencies that include neutropenia as part of a syndrome, such as SCID due to AK2 deficiency (reticular dysgenesis), or that result in isolated quantitative or qualitative defects of neutrophils often present in the neonatal period. This reflects the essential role of neutrophils in phagocytosing pathogenic bacteria and fungi and eliminating them by oxidative and nonoxidative mechanisms within the phagosome (Dinauer, 2016). Bacterial infections, such as bacteremia with gram-negative organisms such as *E. coli* or *Pseudomonas aeruginosa* or gram-positive organisms such as *Staphylococcus aureus*, are frequent with neutrophil disorders. Delayed umbilical cord separation and omphalitis are important clinical signs that should lead to evaluation for neutrophil deficiency, such as leukocyte adhesion defect, which is most commonly due to biallelic mutations of the *CD18* gene. An important clue to leukocyte adhesion defect is that the neutrophil count is always elevated above normal values, even in the absence of infection or other inflammatory stimuli. Chronic granulomatous disease (CGD) is due to mutations of genes encoding the phagocyte oxidase system, which is required for oxidative killing within the phagosome. The clinical infections characteristic of CGD, such as deep tissue infections with bacteria or fungi, can present during the neonatal period, although in most cases this occurs later in infancy.

Although relatively rare, monogenic immune deficiencies of innate immune cell signaling may present in the neonatal period with severe gram-positive or gram-negative bacterial infections or fungal infections. Among the best characterized are biallelic mutations of the genes encoding MyD88 or IL-1 receptor–associated kinase 4 (IRAK-4), which are cytoplasmic proteins that are required for both TLR and IL-1 receptor family (IL-1R) signaling (von Bernuth et al., 2012). The lack of IL-1R signaling results in an impaired febrile response, and the absence of any fever in a neonatal patient with a severe invasive bacterial or fungal infection should lead to an evaluation for these disorders. A useful screening test for MyD88 or IRAK-4 deficiency is to evaluate peripheral blood mononuclear cells for their production of TNF- α in response to incubation with TLR ligands, such as endotoxin, flagellin, or oligodeoxynucleotides containing unmethylated CpG residues. Such production is markedly impaired or absent in these patients.

Immunization

Other than access to proper sewage systems and clean drinking water, immunization is the most effective biomedical intervention to reduce early-life infection. Approaches to protecting the newborn and the young infant from infection include maternal immunization, with subsequent passive transfer of maternal antibodies to the fetus/newborn, as well as early-life immunization of the newborn and the young infant. Each of these approaches has important advantages and potential challenges.

Maternal Immunization

Maternal immunization can provide substantial benefits for both the mother and the infant by induction before or during pregnancy of maternal IgG antibody that can be transferred to the fetus during the last trimester of pregnancy and protect both the fetus and the mother against postpartum morbidity and death. Although immunization before or during pregnancy has been effective in preventing several specific neonatal infections, including diphtheria, pertussis, tetanus, hepatitis B, and rabies (Omer, 2017), there have

• BOX 36.1 Summary of Recommendations for Immunization During Pregnancy

Live Virus Vaccines

- Influenza (live attenuated influenza vaccine) – contraindicated
- Measles – contraindicated
- Mumps – contraindicated
- Rubella – contraindicated
- Yellow fever – safety not established (travel to high-risk areas only)
- Varicella – contraindicated

Inactivated Virus Vaccines

- Hepatitis A vaccine – consider if high risk of exposure
- Influenza vaccine – recommended
- Rabies vaccine – consider if indicated

Inactivated and Recombinant Bacterial Vaccines

- Cholera vaccine – to meet international travel requirements
- Meningococcal polysaccharide vaccine – consider if indicated
- Plague vaccine – selective vaccination of exposed persons
- Typhoid vaccine – safety not established
- Pneumococcal polysaccharide vaccine – consider if indicated
- Tetanus–diphtheria vaccine – consider if indicated
- Hepatitis B vaccine – consider if indicated
- Meningococcal conjugate vaccine – consider if indicated

Pooled Immune Serum Globulins

- Hepatitis A – postexposure prophylaxis
- Measles – postexposure prophylaxis

been theoretical concerns with this approach. For example, immunization during pregnancy might result in vaccine antigens interacting with vital fetal or placental tissues that could potentially lead to unanticipated maternal or fetal morbidity. Maternal immunization can also induce an antibody response in the fetus, as has been demonstrated with tetanus toxoid (Gill et al., 1983), and potentially could induce undesirable immunologic side effects (e.g., immunologic unresponsiveness or tolerance) in the infant. In practice, none of these concerns has been documented as major issues with maternal immunization with inactivated vaccines. Limitations of and challenges for maternal immunization include (1) incomplete adherence of pregnant mothers to outpatient visits/immunization and (2) preterm birth, affecting approximately 11% of all global deliveries such that preterm newborns may be born before transfer of protective maternal antibodies.

The priorities for active vaccination during pregnancy rest on assessment of maternal risk of exposure, the maternal–fetal–neonatal risk of disease, and the potential risks from the specific vaccine. A summary of recommendations for immunizations during pregnancy is provided in Box 36.1. In general, immunization with live viral vaccines during pregnancy is not recommended, and it is preferred that live viral vaccinations be performed before pregnancy occurs. However, rare instances may occur in which live viral vaccine administration is indicated. For example, if a pregnant woman travels to an area with high risk of yellow fever, administration of that vaccine might be indicated because of the susceptibility of the mother and the fetus, the probability of exposure, and the risk of the mother and fetus contracting the disease.

Immunization during pregnancy with tetanus toxoid to prevent neonatal tetanus illustrates the importance of the maternal immunization strategy in less developed countries where neonatal tetanus

remains prevalent. Such immunization is a cost-effective method for preventing neonatal tetanus, with two or more doses appearing to be effective in reducing both the incidence of disease and death resulting from it (Demicheli et al., 2015). Older studies suggest that maternal tetanus toxoid immunization may provide up to 10 years of protection for infants (Schofield, 1986; Gill et al., 1991; Vandelaer et al., 2003).

Maternal immunization during pregnancy with acellular pertussis vaccine has become an important strategy to address the worldwide problem of pertussis of the neonate and the young infant (Bento and Rohani, 2016; Sobanjo-Ter Meulen et al., 2016). Prevention of pertussis in the neonate and the young infant is paramount as infection can rapidly progress from a nondescript mild afebrile illness, with coryza, mild cough, and sneezing, and no pulmonary findings on physical examination to a life-threatening pneumonia with pulmonary hypertension (Cherry, 2016). The complete replacement in more developed countries of the more reactogenic whole-cell pertussis vaccine with the better tolerated acellular vaccine, which induces less durable immune responses and modifies the disease but not the acquisition of infection, is likely an important contributor to the resurgence of neonatal/young infant pertussis (Sobanjo-Ter Meulen et al., 2016). In the United States, all pregnant women are recommended to receive the acellular pertussis vaccine (usually given as part of a Tdap immunization) between 27 and 36 weeks' gestation, a strategy that aims to maximize the levels of pertussis-specific IgG that are transferred to the fetus by birth (Omer, 2017). Acellular pertussis vaccine is recommended with each pregnancy to ensure that adequate pertussis-specific IgG titers are present late in gestation. The use of a similar maternal vaccination strategy in the United Kingdom has been estimated to be 90% effective in preventing the acquisition of pertussis by infants aged 2 months or younger (Amirthalingam et al., 2014; Dabrera et al., 2015). However, there is evidence that maternal immunization late in pregnancy may also blunt the infant's pertussis-specific antibody response to the primary immunization doses of acellular vaccine (Ladhani et al., 2015). Whether such blunting is clinically significant and puts older infants at greater risk of acquisition of pertussis is unclear, particularly since this effect has not been observed following the toddler booster dose of acellular vaccine (Munoz et al., 2014). Clearly, there remain many major gaps in our knowledge of immune protection of humans from infection and disease with *Bordetella pertussis* that need to be filled so as to develop more effective pertussis vaccines (Vaughan et al., 2014; Plotkin, 2016).

Immunization of the Prematurely Born Infant

In general, preterm neonates of 24 weeks' gestation or greater produce antibody to T-dependent protein antigens such as tetanus and diphtheria toxoid and inactivated poliovirus contained in combination vaccines as do term neonates when the vaccines are administered at 2, 4, and 6 months of age (Gagneur et al., 2015). However, the antibody response to acellular pertussis vaccine, particularly for pertussis toxin, is reduced in preterm infants when they are immunized at the standard chronologic age, and this reduction in the antibody response remains evident at 5 to 6 years of age. Although the clinical significance of these decreased responses to acellular pertussis vaccine remain unclear, it has been suggested that prematurely born children might benefit from an earlier administration of the fifth dose of acellular pertussis vaccine, which is usually given between 5 and 6 years of age (Esposito et al., 2002).

The antibody response in premature infants to multiple doses of hepatitis B vaccine, initially administered at birth, is reduced

compared with that of term infants (Lau et al., 1992). The ultimate antibody titers are substantially increased if immunization of the premature infant is delayed until 5 weeks of age, indicating the importance of postnatal age rather than of a particular body weight (Kim et al., 1997). The benefits of such a delay for long-term hepatitis B-specific antibody titers are evident for at least the first 3 years of life (Linder et al., 2002). The approach for hepatitis B immunization of the prematurely born infant whose mother is hepatitis B surface antigen (HBsAg) positive is described in the section entitled **Neonatal Immunization**.

In most studies the *Haemophilus influenzae* type b (Hib) polysaccharide antibody levels after three doses of Hib polysaccharide–tetanus conjugate vaccine have been significantly less in premature infants than in term infants when vaccination is begun at 2 months of age (Greenberg et al., 1994). This reduced antibody response especially applies to premature infants with chronic lung disease (Washburn et al., 1993), whose antibody titers are likely to be depressed by systemic treatment with glucocorticoids for the treatment of bronchopulmonary dysplasia. Nevertheless, protective antibody responses are ultimately achieved following the third vaccine dose in most cases.

The antibody response of premature infants to the 13-valent pneumococcal conjugate vaccine (Prevnar 13) with a schedule of 2, 3, 4, and 12 months of chronologic age resulted in lower geometric mean titers than in term infants following the initial doses; however, most infants still achieved protective levels of antibody following the booster dose. Thus a four-dose regimen is recommended for premature infants consisting of three primary doses and one booster dose of the conjugate vaccine (Gagneur et al., 2015).

Collectively, these studies support the general approach for initiating the routine childhood vaccine series at 2 months of chronologic age regardless of the gestational age at birth. Extra or earlier administration of booster doses may be considered for some vaccines. More detailed recommendations are available from the Committee on Infectious Disease of the American Academy of Pediatrics at <http://reader.aappublications.org/red-book-30th-edition-2015/>.

Neonatal Immunization

Hepatitis B vaccine, polio vaccines, and bacille Calmette–Guérin (BCG) vaccine are the only childhood vaccines routinely given at birth. Immunization shortly after birth offers important logistic advantages for providing protection against infectious diseases as birth is the most reliable point of healthcare contact worldwide, especially in less developed countries (Demirjian and Levy, 2009). However, the response of the neonate to vaccination with T-independent polysaccharide vaccines, such as unconjugated pneumococcal vaccine, is negligible and the humoral response to T-dependent antigens, such as proteins and protein–polysaccharide conjugate vaccines, is less robust and durable than that of the adult (Siegrist, 2007). Thus extending neonatal immunization to involve other routine childhood vaccines may require the development of formulations that are more immunogenic when administered in the first few days after birth.

The Advisory Committee on Immunization Practices (ACIP) and American Academy of Pediatrics (AAP) both recommend universal immunization of infants to protect against perinatal transmission of hepatitis B virus (HBV) and chronic HBV infection. Chronic HBV infection occurs in approximately 90% of infected infants and is associated with hepatocellular carcinoma and cirrhosis leading to end-stage liver disease. In all medically stable infants

born to women with a negative test result for HBsAg and weighing more than 2000 g at birth, a hepatitis immunization schedule should be initiated in the newborn period before hospital discharge. Only single-antigen hepatitis B vaccines should be used for the birth dose (Mast et al., 2005). All infants regardless of gestational age at the time of birth and whose mothers have a positive test result for HBsAg should receive passive immunization with hepatitis B Ig and active immunization with a single-antigen hepatitis B vaccine within 12 hours of birth. Repeated vaccinations are given at 1 to 2 months of age and again at 6 months. For premature infants weighing less than 2000 g and born to HBsAg-positive mothers, the birth dose is not counted as part of the vaccine series, and these infants should receive a total of four doses of the vaccine as part of the primary series (Waitz et al., 2015). Special efforts should be made to complete the hepatitis B vaccination schedule within 6 to 9 months in populations of infants with high rates of childhood hepatitis B (Peter, 1994).

BCG, the live attenuated *Mycobacterium bovis*, is the most commonly administered vaccine in world history, with billions of doses given to date. A metaanalysis of randomized controlled trials of BCG immunization of the neonate and the young infant indicated that the vaccine reduced the risk of tuberculosis by more than 50% and that this protection appeared to persist for 10 years after vaccination (Colditz et al., 1995). The mechanisms underlying this protective effect remain unclear, and defining such mechanisms has been complicated by the use in human vaccination programs of more than 10 different BCG substrains, produced at different locations, that may differ in their biologic properties and immunogenicity (Frankel et al., 2016). An important source of BCG and other vaccines for low-income countries, many of which have high rates of endemic tuberculosis, has been the Expanded Program on Immunization of the World Health Organization. BCG appears to protect not only against its target pathogen (*Mycobacterium tuberculosis*) but also against a broad array of microorganisms (Aaby et al., 2014). Such heterologous (“nonspecific”) effects may be particularly important for newborns and infants as the heterologous benefit of BCG appears to be greatest when given early in life (Pettengill et al., 2014; Goodridge et al., 2016). Although BCG administration to neonates and infants has generally been very safe, severe disseminated BCG infection (BCGosis) can occur in infant patients who have SCID, chronic granulomatous disease, or mendelian susceptibility to mycobacterial disease; for example, genetic deficiencies of IL-12 receptor, IL-12 p40, IFN- γ receptor 1 or receptor 2, or STAT1 (loss-of-function mutations) (Norouzi et al., 2012). Thus BCG vaccination is contraindicated in patients known to have or suspected of having these PIDs or who have a family history of such disorders.

A growing appreciation of distinct immunity with age has prompted efforts to develop vaccines that may induce robust protection in the newborn and the young infant (Sanchez-Schmitz and Levy, 2011). One approach for improving the response to neonatal vaccination has been to combine vaccine antigens with adjuvants to enhance immune responses, focusing on adjuvants for which human neonatal APCs have robust adult-like responsiveness in vitro (Sanchez-Schmitz, 2011; Dowling and Levy, 2014). A promising example of this approach is to combine TLR agonists that are particularly active in early life such as imidazoquinoline TLR7/8 agonists with the 13-valent pneumococcal polysaccharide protein conjugate vaccine (Prevnar 13). Immunization of 1-day-old nonhuman primates with the combination of TLR7/8 agonist and Prevnar 13 resulted in a 10-fold to 100-fold increase in specific antibody titer that was associated with robust increases in the CD4 T-cell responses to the vaccine protein conjugate

(Dowling et al., 2017). A similar approach could be potentially used for other inactivated vaccines that currently are routinely administered at 2 months of age.

Overall, there is compelling rationale to characterize early-life immune ontogeny to provide fresh perspectives on neonatal health and disease and inform novel approaches to protect the fetus and young infant (Kollmann et al., 2017).

Viral Infections of the Fetus and Newborn

MARK R. SCHLEISS AND KETZELA J. MARSH

KEY POINTS

- Viral infections of the fetus and newborn are common problems in neonatology practice and must be considered in the differential diagnosis of newborns with intrauterine growth retardation, physical examination and laboratory abnormalities, and illness in the newborn period.
- The diversity of fetal and neonatal viral infections is vast. The depth and breadth of viral disease are extensive and the differential diagnosis broad.
- Clinicians should consider specific causes and not rely on broad-based categorical consideration of Toxoplasmosis, Other, Rubella, Cytomegalovirus, Herpes Simplex Virus (TORCH) syndromes, since specific signs, symptoms, and findings are quite diverse, depending on the pathogen being considered.
- Antiviral therapies are now available for many of these pathogens, underscoring the importance of making a specific diagnosis.
- Laboratory studies focused on virologic detection, driven in most cases by molecular assays, are much more precise and reliable than serologic diagnosis.

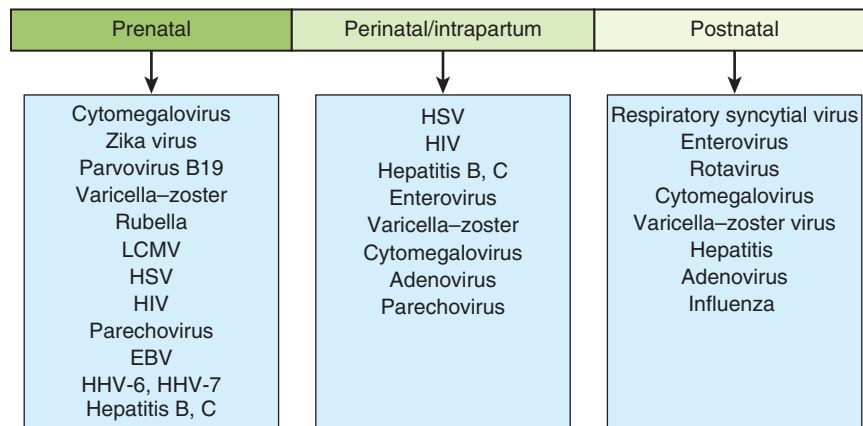

Viral infections of the fetus and newborn are common and underrecognized. Given the life-threatening nature of invasive bacterial disease in the neonate, the identification of viral infections is often relegated to a matter of secondary importance. However, identifying viral infections can also be a matter of great urgency, because antiviral agents are available for many of the most common infections. Accordingly, an appropriately high index of clinical suspicion in identifying neonatal viral infections can be lifesaving. Moreover, identification of viral disease in the neonate may be of great prognostic significance, particularly for identification of infants at high risk of long-term neurodevelopmental issues. Making a diagnosis of a neonatal viral infection can help to direct and focus anticipatory management by the child's pediatrician during the course of well-child care. This chapter reviews the epidemiology, pathogenesis, diagnosis, and short-term and long-term clinical management of many of the more common congenital and perinatal viral infections encountered in neonates.

One of the great challenges in the evaluation of viral disease in the newborn is the ascertainment of the timing of acquisition of infection. Some infections can be acquired either in utero or

in the early postnatal period. In this chapter, *congenital infection* is defined as any infection acquired in utero. *Perinatal infections* are defined as those acquired intrapartum, typically during the labor and delivery process. *Postnatal infections* are acquired in the postpartum period and are defined as infections acquired after delivery through the first month of life. In some situations, correctly identifying the timing of acquisition of infection can have substantial consequences, not only for the care of the infant but for predicting the long-term prognosis. Fig. 37.1 outlines the most common timing of acquisition of neonatal viral infections with an emphasis on the relative importance of the many viruses that can be acquired congenitally, perinatally, or postnatally. There is considerable overlap across categories for some viral infections that can be transmitted at any of these time points, and this will be considered on a pathogen-by-pathogen basis.

General Diagnostic Approach

Clinicians caring for newborns have long recognized that there are some common clinical manifestations that suggest the presence of a congenital or perinatal viral infection. These manifestations include evidence of intrauterine growth restriction (IUGR), microcephaly, hydrops fetalis, hepatomegaly, splenomegaly, pneumonitis, bone lesions, rashes, and hematologic abnormalities (Box 37.1). Because congenital viral infections are commonly encountered in neonatology practice (Alpert and Plotkin, 1986), it is appropriate for clinicians to have a high index of suspicion in any newborn with suggestive signs or symptoms. However, caution should be taken to thoughtfully consider diagnostic possibilities suggested by the history and physical examination, recognizing the specific etiologic diagnoses compatible with an infant's presentation. The unfortunate continued use of the term *TORCH titers* in the clinician's diagnostic approach to a symptomatic neonate oversimplifies and seriously underestimates the diversity of neonatal viral infections encountered in practice. The acronym *TORCH*, first coined by Nahmias et al. (1971), stands for *toxoplasmosis*, *other* infections, *rubella*, *cytomegalovirus* (CMV), and *herpes simplex virus* (HSV). Numerous variants of this acronym have been suggested in the past 4 decades (Kinney and Kumar, 1988; Ford-Jones and Kellner, 1995; Ronel et al., 1995; Tolan, 2008; Shet, 2011; Neu et al., 2015). Unfortunately, numerous clinical laboratories continue to offer the "TORCH panel," typically consisting of serologic tests

• **Fig. 37.1** Relative importance of neonatal viral infections related to the timing of acquisition of infection. Viruses are listed in declining relative order of importance relative to prenatal, perinatal (intrapartum), and postnatal timing of typical infection. Some neonatal virus infections (e.g., cytomegalovirus) can be substantial causes of disease whether acquired during gestation or acquired postpartum, whereas others (e.g., respiratory syncytial virus) are typically acquired in the postnatal period. *EBV*, Epstein–Barr virus; *HHV*, human herpesvirus; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *LCMV*, lymphocytic choriomeningitis virus.

• **BOX 37.1** Clinical Features Commonly Associated With Congenital Viral Infections in Neonates

- Intrauterine growth restriction
- Nonimmune hydrops fetalis
- Echogenic bowel (prenatal ultrasonography)
- Placental villitis, chorioamnionitis
- Hepatosplenomegaly
- Jaundice (>20% direct-reacting bilirubin)
- Hemolytic anemia
- Purpura, ecchymoses, and petechiae
- Skeletal defects (“celery stalking”)
- Microcephaly and hydrocephaly
- Intracranial calcification
- Neuronal migration defects
- Pneumonitis
- Myocarditis
- Cardiac abnormalities
- Chorioretinitis
- Keratoconjunctivitis
- Cataracts
- Glaucoma

for toxoplasmosis, syphilis, HSV, CMV, and rubella. This acronym has outlived its usefulness (Lim and Wong, 1994) and should be discarded from clinical parlance, on the basis of the following considerations:

- Measurements of immunoglobulin G (IgG) antibody titers virtually always simply reflect transplacental maternal antibody and provide little information of relevance to the infant’s infection status. With the exception of the identification of antibodies to *Treponema pallidum*, which is always of interest and significance, antibodies against the other members of the TORCH panel are often of little diagnostic importance.
- Congenital and perinatal infection can occur with HSV and CMV, even in the face of preconception maternal immunity. Thus the finding of IgG antibody against these viruses in a

TORCH titer is neither diagnostic of infection nor reassuring with regard to protection against that infection.

- Highly sensitive virologic and molecular tools are available to identify virtually all pathogenic viruses. These tools include standard culture and nucleic acid identification techniques, typically based on polymerase chain reaction (PCR) amplification of viral nucleic acids. Such studies can facilitate rapid pathogen-specific diagnosis; therefore the diagnosis of neonatal viral disease should depend on diagnostic virology, not serology.
- Most importantly, the use of the acronym *TORCH* vastly underemphasizes the great diversity of viral pathogens that are associated with infections in the newborn. A list of the myriad of viral pathogens that have been reported to cause congenital infection and disease is included in Box 37.2. A discussion of many of the more unusual viral causes of congenital infection is beyond the scope of this chapter, but the list in Box 37.2 underscores the diversity of agents associated with fetal infection. A recent travel history or recent emigration might suggest consideration of some of these more unusual agents.

Rather than rely on a large battery of serologic tests, the astute clinician can typically formulate a focused differential diagnosis of a suspect neonatal or congenital viral infection with the history and physical examination, followed by the use of specific diagnostic studies emphasizing virologic and not serologic methods. Important questions include: What was the overall health of the mother during her pregnancy? What is her age and marital status (e.g., young, unmarried women have a higher risk of acquiring primary genital HSV infection)? What is her immunization history? Has she had chickenpox? Did she have other common childhood viral infections? What part of the world is she from? Is there a recent travel history? Are there potential animal exposures (e.g., exposure to cat litter or consumption of undercooked meat might suggest toxoplasmosis; exposure to rodents might suggest lymphocytic choriomeningitis virus [LCMV])? Does she have other children, and, if so, what are their ages, overall health status, and histories of group day care attendance? Have there been recent illnesses in the household? What time of year is it? (For example, respiratory syncytial virus [RSV] and enterovirus infections have characteristic seasonality in temperate zones.) What are her occupational

exposures? Did she have any symptomatic infectious illnesses during pregnancy? The answers to these types of questions, considered in the context of the infant's physical examination, can direct the next steps in establishing a definitive etiologic diagnosis.

Some of the classic presentations of the more common perinatal viral infections are reviewed in [Table 37.1](#). There can be considerable overlap of these clinical features across the different infectious categories listed; for example, the “blueberry muffin” rash of

TABLE 37.1 Clinical Findings in Selected Congenital and Perinatal Infections That Suggest a Specific Diagnosis

| Congenital Infection | Findings |
|--|---|
| Rubella | Cataracts, cloudy cornea, pigmented retina; petechiae with “blueberry muffin” rash; bone defects with longitudinal bands of demineralization (“celery stalking”); cardiovascular malformations (patent ductus arteriosus, pulmonary artery stenosis); sensorineural hearing loss; hydrops |
| Cytomegalovirus infection | Microcephaly with periventricular calcifications; chorioretinitis; petechiae with thrombocytopenia; jaundice; sensorineural hearing loss; bone abnormalities; abnormal dentition, hypocalcified enamel |
| Herpes simplex virus infection | Skin vesicles, keratoconjunctivitis, acute central nervous system findings (seizures), hepatitis, pneumonitis |
| Zika virus infection | Microcephaly, intracranial calcifications, retinitis, hearing loss |
| Parvovirus B19 infection | Hydrops, ascites, hepatomegaly, ventriculomegaly, hypertrophic cardiomyopathy, anemia |
| Varicella–zoster virus infection | Limb hypoplasia, dermatomal scarring in a cicatricial pattern, gastrointestinal tract atresia |
| Lymphocytic choriomeningitis virus infection | Hydrocephalus, chorioretinitis, intracranial calcifications |

congenital rubella syndrome (CRS) may be indistinguishable from that of congenital CMV infection, and both syndromes can include sensorineural deafness. The presence of brain calcifications and/or microcephaly, although nonspecific, should always suggest a differential diagnosis that includes CMV, toxoplasmosis, LCMV, parechoviruses, and Zika virus. Because neuroradiologic studies cannot reliably distinguish these entities, definitive diagnostic virology is necessary. Specific viral pathogens, their basic virology, the clinical manifestations of diseases they cause in the newborn, management strategies, and prospects for prevention are considered on a pathogen-specific basis in the remainder of this chapter.

Herpesviridae

Currently there are eight recognized human herpesviruses (HHVs), which are subdivided into three categories on the basis of aspects of viral biology, pathogenesis, and clinical presentations. These categories are the α -herpesviruses, consisting of HSV-1, HSV-2, and varicella–zoster virus (VZV); the β -herpesviruses, which include CMV and the roseola viruses HHV-6 and HHV-7; and the γ -herpesviruses, which include Epstein–Barr virus (EBV) and Kaposi sarcoma–associated herpesvirus (KSHV). Perinatal and congenital infections with this family of viruses have been the subject of several reviews ([Enright and Prober, 2004](#); [Schleiss, 2009](#); [Bialas et al., 2015](#)). Remarkably, all of these agents have been implicated in various degrees as causes of clinically important congenital and

perinatal infections, although these associations are less well studied for the γ -herpesviruses.

Herpes Simplex Virus Infections

HSV-1 and HSV-2 are highly related viruses. Although classically HSV-1 has been identified as a cause of oral infections (gingivostomatitis and pharyngitis), and HSV-2 has been implicated as the most common virus associated with genital herpes, in recent years these distinctions have become blurred. The greatest risk for the newborn is in the context of a first-time episode of maternal genital HSV infection occurring during pregnancy. The entity of neonatal herpes is reviewed in the following section, along with current management approaches for this infection.

Virology, Epidemiology, and Clinical Manifestations of Herpes Simplex Virus Disease

HSV-1 and HSV-2 demonstrate a high degree of similarity, both at the molecular level and in their clinical manifestations. The degree of genetic relatedness of these two viruses is approximately 45%, and the genome structures and morphology of the virion (virus particle) are virtually identical (Kieff et al., 1972). HSV-1 and HSV-2 are both acquired predominantly at mucosal surfaces and require intimate contact for transmission. After primary infection in epithelial cells, intra-axonal trafficking of viral DNA to the dorsal root ganglia results in the establishment of latency. The latent state is characterized by the cessation of virtually all gene transcription, except for the latency-associated transcript, which is expressed in the dorsal root ganglia even as the virus maintains a quiescent state (Taylor et al., 2002; Steiner et al., 2007; Nicoll et al., 2016). The function of the latency-associated transcript is unknown, but it might involve a novel ribonucleic acid (RNA)-mediated mechanism, because there does not appear to be a protein product associated with the transcript (Umbach et al., 2008). After a number of triggers, including ultraviolet radiation, stress, and immunosuppression, the virus reactivates at the level of the dorsal root ganglia and initiates a cascade of viral transcription that leads to the production of infectious virus, which can traffic via the axon to the cutaneous surface or ocular surface, producing lesions (Toma et al., 2008). The recrudescence of HSV lesions, usually manifested as vesicular or ulcerative lesions at the site of primary infection, can in turn lead to person-to-person transmission, including maternal-fetal and maternal-infant transmission. Asymptomatic or subclinical shedding of virus is well documented, particularly in the setting of genital herpes.

A wide variety of disease syndromes are associated with primary and recurrent HSV infection. Classically HSV-1 has been described as causing disease “above the belt,” whereas HSV-2 is associated with disease “below the belt.” The finding of HSV-2 antibodies in seroprevalence studies is generally viewed as indicative of genital herpes, and in the pregnant patient it can be considered to be diagnostic of genital herpes. The most common disease associated with HSV infection is herpetic gingivostomatitis, characterized typically by perioral and intraoral lesions involving the pharyngeal mucosa. HSV infection of the oropharynx may present in adolescence as herpetic pharyngitis (McMillan et al., 1993); it can be indistinguishable from other causes of pharyngitis. Other common manifestations of HSV infection include primary cutaneous infection, which can manifest itself as herpes gladiatorum or as a herpetic whitlow (Johnson, 2004; Wu and Schwartz, 2009; Sanders and Garcia, 2014), and eczema herpeticum, a serious illness that produces systemic symptoms (Bussmann et al., 2008). Exposure to an

individual (including a healthcare provider) with any of these cutaneous manifestations of HSV infection could potentially put a newborn at risk of acquisition of infection if care is not taken to protect the newborn. In contrast, HSV encephalitis is unlikely to be transmitted person-to-person, although HSV it is the most common sporadic cause of viral encephalitis in North America (Kaewpoowat et al., 2016). HSV encephalitis can be associated with primary infection or reactivation of latent infection. It is most commonly associated with HSV-1 (Baringer, 2008). Genital HSV infection is also an important risk factor for acquisition of human immunodeficiency virus (HIV) infection in the developing world (Corey et al., 2004).

From the pediatrician's perspective the most important manifestation of HSV disease is maternal genital herpes. Genital herpes can be associated with either HSV-1 or HSV-2. HSV is the most common cause of genital ulcerative disease in the developed world, and the prevalence has increased steadily in recent years (Fleming et al., 1997). Genital herpes is characterized by blisters, ulcers, or crusts on the genital area, buttocks, or both. Typically, symptomatic disease manifests itself with a mixture of vesicles, ruptured vesicles with resulting ulcers, and crusted lesions. Systemic flulike symptoms such as headache, fever, and swollen glands can accompany an outbreak of genital herpes, particularly during primary infection. Other symptoms include dysuria, urinary retention, vaginal or penile discharge, genital itching, burning or tingling, and groin sensitivity. Genital lesions differ in number, are painful in nature, and if untreated persist for up to 21 days (Whitley et al., 1998). Primary genital herpes during pregnancy can be associated with disseminated maternal disease, including severe hepatitis, disseminated intravascular coagulation (DIC), and central nervous system (CNS) infection (Young et al., 1976; Gelven et al., 1996; Frederick et al., 2002; Allen and Tuomala, 2005; Dodd et al., 2015). It has been recognized in recent years that many individuals with genital herpes are asymptomatic and unaware of their status (Wald et al., 2000; Groves, 2016). Therefore a negative maternal history of HSV *should not* dissuade the clinician from considering the possibility of neonatal herpes in an infant with compatible signs and symptoms. Patients with recurrent symptomatic episodes continue to shed virus in between episodes, even after lesions have healed and crusted over (Leone, 2005). This information has important implications for the continued evolution of the HSV epidemic in the United States. Because individuals with asymptomatic genital herpes shed virus frequently in the absence of lesions, all HSV-2-seropositive individuals are probably at risk of transmitting infection in a setting of sexual activity, labor and delivery, and intimate contact.

Neonatal Herpes

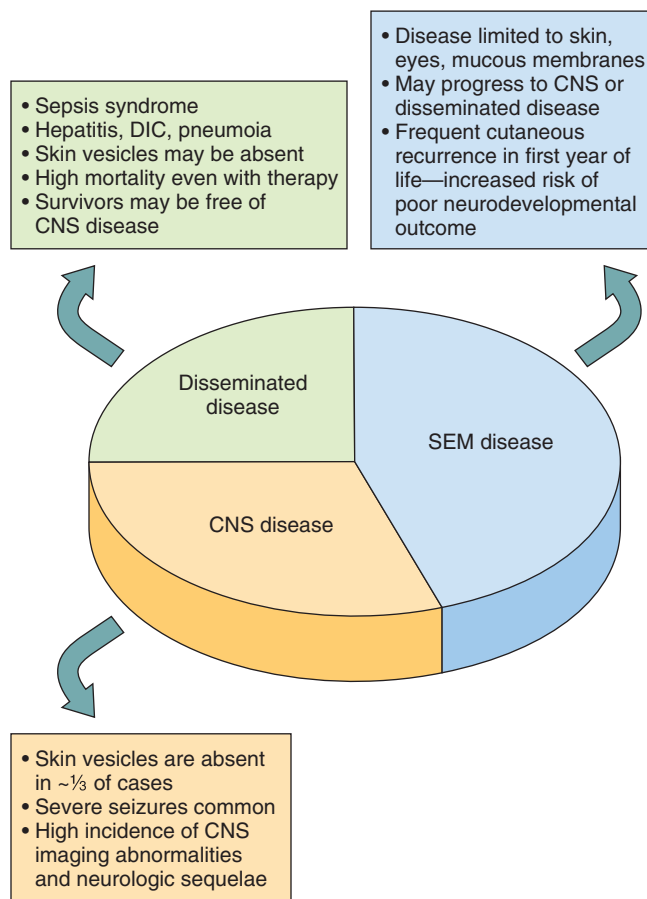

In the United States the reported incidence of neonatal herpes ranges from 1 in 2500 births to 1 in 8000 births (Whitley, 2004; Kimberlin, 2005; Corey and Wald, 2009; Chernes et al., 2012; Pinninti and Kimberlin, 2014). Approximately 70%–85% of neonatal herpes simplex infections are caused by HSV-2 (Kimberlin et al., 2001). It is estimated that 22% of pregnant women are infected genitally with HSV but that most of these women are unaware of their infection (Brown et al., 2005; Pinninti and Kimberlin, 2014). Approximately 2% of women acquire primary HSV infections during pregnancy (Brown et al., 2005). Most cases occur in neonates born to women who were recently infected, rather than to women with histories of recurrent genital herpes. Primary infection late in pregnancy poses a higher risk of transmission to the infant than do primary infections occurring before or

early in pregnancy, suggesting that the evolution of a maternal antibody response confers some measure of protection for the infant (Brown *et al.*, 2003; Caviness *et al.*, 2008a). In particular, the greatest risk of transmission to the fetus and the newborn occurs when an initial maternal infection is contracted in the second half of pregnancy (Straface *et al.*, 2012). Primary genital herpes infection in a pregnant mother results in an estimated attack rate of 33%–60% for her infant, whereas recurrent maternal infection results in a 1%–3% attack rate (Prober *et al.*, 1987; Arvin, 1991; Brown *et al.*, 1997; Pinninti and Kimberlin, 2014). Approximately 90% of these women are undiagnosed, because they are asymptomatic or have symptoms that are incorrectly attributed to other vulvovaginal disorders.

Rarely, cases of intrauterine infection have been described; these are often associated with overwhelming primary maternal infection and usually result in fetal demise. On occasion, placentitis is also observed (Florman *et al.*, 1973; Hutto *et al.*, 1987; Baldwin and Whitley, 1989; Chatterjee *et al.*, 2001; Barefoot *et al.*, 2002; Vasileiadis *et al.*, 2003; Low *et al.*, 2012; Pfister *et al.*, 2013). Most HSV infections in newborns are acquired intrapartum and related to the presence of virus in the maternal genital tract. Neonatal acquisition of HSV from an individual other than the mother, such as from a recurrent oropharyngeal lesion, is unusual (Linnemann *et al.*, 1978; Light, 1979; Yeager *et al.*, 1983). Neonatal HSV infection has been described as a complication of ritual circumcision (Rubin and Lankowsky, 2000; Gesundheit *et al.*, 2004; Leas and Umscheid, 2015). Approximately 85% of infants with neonatal HSV infection acquire the infection from the maternal genital tract at the time of delivery, but only 15%–30% of mothers who give birth to neonates with neonatal HSV infection have a known history of genital HSV infection (Whitley, 1988). Intrapartum interventions that have the risk of penetrating fetal skin, such as scalp electrode monitoring, increase the risk of transmission to the infant (Golden *et al.*, 1977; Parvey and Ch'ien, 1980).

Neonatal herpes can have devastating long-term consequences, making early recognition of paramount importance. Most newborns with perinatal or postnatal HSV infection are normal at birth. Illness typically develops after 3 days of age; therefore the presence of skin lesions, oral ulcers, and other signs and symptoms in the first 72 hours of life can suggest diagnoses other than HSV. Premature infants appear to be at greater risk, possibly because of reduced transplacental transfer of protective antibody. Approximately 40%–50% of affected infants are of less than 36 weeks' gestational age (Whitley, 1988). Although a history of maternal cervical, vaginal, or labial lesions should be sought when neonatal HSV infection is being considered in the differential diagnosis, overt herpetic disease in the maternal genital tract is evident in only approximately one-third of patients (Overall, 1994). In the remaining two-thirds of cases, infection occurs in the context of asymptomatic maternal genital tract shedding of HSV.

Infection can manifest itself in newborns in one of three forms: disease limited to the skin, eye, or mucous membrane (SEM disease); disease involving the CNS; or disseminated HSV infection, frequently manifesting itself as a sepsis-like syndrome, with pneumonia, hepatitis, and viremia (Fig. 37.2; Whitley, 2004; Kimberlin, 2005). There can be overlap in these syndromes; for example, an infant with disseminated disease may initially have only skin lesions. The relative proportion of infants with disseminated disease has been declining in recent years, probably because earlier recognition and treatment of SEM disease have resulted in more timely intervention with antiviral therapy. Disseminated disease usually begins toward the end of the first week of life. Skin vesicles may be an early sign,

• **Fig. 37.2** Characteristic presentations of neonatal herpes simplex virus (HSV) infection. Approximately 45% of neonatal HSV infections manifest themselves as skin, eye, or mucous membrane disease (SEM disease), 25% as disseminated disease, and 30% as central nervous system (CNS) disease. Characteristic features of each subtype of neonatal HSV are listed (arrows). Disease may span categories; for example, infants with SEM disease may progress to disseminated or CNS disease, and infants with CNS disease may develop skin vesicles later in the hospital course, although up to one-third of infants with CNS disease never have cutaneous manifestations. Overall, approximately half of all infants with neonatal HSV disease will have CNS involvement (CNS disease or disseminated disease with CNS involvement). DIC, Disseminated intravascular coagulation.

but they are entirely absent in almost half of patients. The scalp should be inspected carefully, particularly near the site of insertion of fetal scalp electrodes, because such lesions are easy to overlook. Systemic symptoms, although initially insidious in onset, progress rapidly. Poor feeding, lethargy, and fever may be accompanied by irritability or seizures if the CNS is involved. These symptoms are followed rapidly by jaundice, hypotension, DIC, apnea, and shock. This form of disease is indistinguishable at its onset from both neonatal enterovirus infection and bacterial sepsis. HSV infection should be considered in the differential diagnosis of infants who have fever during the first 2 weeks of life, because fever can herald the onset of systemic disease. Localized disease may begin somewhat later, with most cases appearing in the second to third weeks of life. When the CNS is the primary site of infection, the skin or eyes may or may not be involved: importantly, up to one-third of infants with documented neonatal HSV CNS disease will never have skin lesions during their clinical course (Thompson and

Whitley, 2011). These infants are lethargic, irritable, and tremulous, and seizures are common and often difficult to control.

Other less common but potentially localized findings are keratoconjunctivitis, chorioretinitis, and pneumonitis, which can manifest itself as a focal infiltrate or as diffuse bilateral disease. Secondary dissemination from a localized infection is common in the neonate. Acute retinal necrosis has been described in a series of infants with neonatal HSV infection (Venincasa et al., 2015). Intracranial hemorrhage, aseptic meningitis, and fulminant liver failure have been described (Kohl, 1994; Schlesinger and Storch, 1994; Greenes et al., 1995; Kohl, 1999; Abzug and Johnson, 2000; Erdem et al., 2002). Some of the less common presentations of neonatal HSV infection can include hydrops fetalis (Anderson and Abzug, 1999; Pfister et al., 2013), laryngitis (Vitale et al., 1993), and supraglottitis (Machin et al., 2013).

Diagnosis

The cornerstone of the diagnosis of neonatal HSV infection is virologic detection; serology is of limited use in the management of suspected infection in the infant, although type-specific serology is useful in evaluation of maternal HSV status in the setting of infants born to women with active genital HSV lesions (Kimberlin et al., 2013). HSV-1 and HSV-2 are both easily recovered by culture of clinical samples. In disseminated disease, virus is present in blood, conjunctivae, respiratory secretions, and urine; it is also present in the CNS in approximately half of patients. In SEM disease the virus can usually be found at the site of disease (i.e., within a vesicle). Definitive microbiologic diagnosis requires growth of the virus in tissue culture or detection of viral nucleic acid by PCR. HSV infection can also be confirmed by immunofluorescence of infected cells with use of HSV-specific antibodies (Sauerbrei, 2016), but this is largely being replaced by PCR. When neonatal herpes is suggested, specimens from the throat, conjunctiva, blood, stool or rectum, and urine should be obtained, as should scrapings of vesicular, pustular, and ulcerative skin lesions. Of these sites, skin and conjunctival samples have the highest yield (Kimberlin et al., 2001).

All infants with presumed neonatal HSV disease should undergo lumbar puncture, even if SEM disease is the only observed clinical manifestation. In some infants, CNS infection may be present but subclinical, and the finding of HSV DNA in the cerebrospinal fluid (CSF) has important therapeutic and prognostic implications. Blood should be sent for viral blood culture or PCR, because viremia is a common finding in neonatal HSV infection (Stanberry et al., 1994; Diamond et al., 1999). If the CNS is involved, evaluation of the CSF usually reveals a lymphocytosis, red blood cells, normal or high protein level, and low or normal glucose level. In addition to viral culture, CSF, blood, skin lesions, and other specimens should be analyzed by PCR for the presence of HSV genome (Ryan and Kinghorn, 2006). Caution should be taken with interpretation of a negative CSF PCR result: many infants with neonatal HSV disease will not have CNS involvement, so a negative CSF PCR result considered in isolation does not exclude the diagnosis of neonatal HSV. PCR of DNA extracted from the dried newborn blood spot has been reported as a way to retrospectively identify HSV infection in young infants (Lewensohn-Fuchs et al., 2003). Some experts recommend a second CSF specimen be obtained for evaluation at the end of antiviral therapy, and it has been reported that persistence of HSV DNA may be a poor prognostic factor and an indication for continuing antiviral therapy (Kimberlin et al., 1996b; Malm and Forsgren, 1999; Mejías et al., 2009). In disseminated disease, transaminase level elevations

consistent with hepatocellular injury are typically present; in severe disease, fulminant hepatitis with hepatic necrosis may be observed.

Infants with CNS disease should undergo neuroradiographic imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Early in the course of illness, imaging may demonstrate nonspecific lack of gray matter–white matter junction differentiation and general signs of encephalitis. Later CT findings include dilated ventricles, parenchymal echogenicity, cystic degeneration, and intracranial calcifications (O'Reilly et al., 1995), whereas MRI images demonstrate a variable appearance (Vossough et al., 2008). Neonatal HSV-2 encephalitis can be multifocal or limited to only the temporal lobes, brainstem, or cerebellum. Deep gray matter structures are involved, and hemorrhage is observed in more than half of patients. In approximately 20% of patients, lesions are seen only by diffusion-weighted imaging. In 40% of patients, watershed distribution ischemic changes are also observed in addition to areas of presumed direct herpetic necrosis. Neurodevelopmental sequelae in infants have been correlated with MRI abnormalities, particularly with diffusion-weighted imaging, which appears to be a valuable prognostic adjunct in neonatal HSV disease (Bajaj et al., 2014). Electroencephalography (EEG) should also be considered in all infants with CNS involvement or with disseminated disease to evaluate them for seizures. EEG findings will be abnormal in approximately 80% of such patients (Kimberlin et al., 2001).

Treatment and Outcomes

The cornerstone of treatment of neonatal HSV disease is the nucleoside analogue *acyclovir*. The development of acyclovir in the 1980s was a watershed event in the management of HSV infection. The use of acyclovir and other antivirals is summarized in Table 37.2. The current recommendation of the American Academy of Pediatrics (AAP) Committee on Infectious Diseases is that neonatal HSV infections should be treated with intravenous (IV) acyclovir at a dosage of 60 mg/kg per day, divided into three doses given every 8 hours, for either 14 days for infants with SEM disease or 21 days for infants with disseminated or CNS disease. Infants with a persistent positive PCR result for HSV from blood or repeated CSF sampling at the end of 21 days of therapy should receive acyclovir for an additional 7 days (Kimberlin et al., 2013). Support for the dosage recommendation was derived from a comparison of the results from an earlier study using standard-dosage acyclovir (30 mg/kg per day) for 10 days (Kimberlin et al., 2001). There is no role for orally administered acyclovir in the initial management of neonatal HSV and no role for topically administered acyclovir in neonatal SEM disease. Herpetic keratoconjunctivitis should receive topical ophthalmic antiviral therapy along with parenteral treatment. In addition to antiviral therapy, appropriate supportive care is essential, with anticipatory management targeting complications of neonatal HSV disease such as seizures, pneumonitis, and hepatic insufficiency. A beneficial role of IV immunoglobulin (IVIG) has been suggested by animal models of neonatal HSV disease (Bravo et al., 1996), but the absence of controlled studies precludes any recommendations in infants.

Even with timely institution of antiviral therapy, the prognosis following neonatal HSV infection is guarded. The mortality rates in infants with localized CNS disease range from 4%–14% with antiviral therapy, and most survivors have long-term neurologic sequelae. Risk factors for increased morbidity and mortality associated with CNS infection include prematurity and seizures on initiation of therapy (Kohl, 1999; Kimberlin et al., 2001). Infants with disseminated disease have a high mortality rate without antiviral

TABLE 37.2 Antiviral Agents Commonly Used in Neonatology Practice

| Antiviral Agent | Indication | Dose, Route of Administration, Duration of Therapy | Comments |
|------------------|---|---|--|
| Acyclovir | Neonatal HSV infection | 60 mg/kg per day, dosing every 8 h intravenously; 21 days for disseminated infection or CNS disease; 14 days for SEM disease | Monitor CBC twice weekly; adjust dosage for renal insufficiency. |
| | Oral suppression following neonatal HSV infection | Efficacy for improving neurodevelopmental outcomes; recommended dosage regimen, 300 mg/m ² per dose, three times a day; duration of therapy, 6 months | Neutropenia observed in half to two-thirds of infants; lesions while receiving suppressive therapy should suggest an acyclovir-resistant strain |
| | VZV infection | 15 mg/kg every 8 h for a minimum of 5 to 7 days; longer courses may be needed for severe end-organ disease (pneumonia, hepatitis) | |
| | VZV postexposure prophylaxis | 10 mg/kg orally four times per day; treat for at least 7 days (from 7 days after the earliest exposure until 14 days after the last exposure) | Use in conjunction with VariZIG. |
| Trifluridine, 1% | HSV ophthalmic disease | Apply as eye drops; one drop every 2 h to the affected cornea while awake; maximum nine drops per day | Treat in consultation with an ophthalmologist. |
| Ganciclovir | Congenital CMV infection; acquired CMV infection | 12 mg/kg per day, dosing every 12 h intravenously; duration of therapy is 6 weeks for prevention of hearing loss; shorter courses of therapy (14 to 21 days) are reasonable for serious end-organ disease | Efficacy against CMV-associated hearing loss in controlled trial; benefits of shorter courses of therapy unknown; neutropenia observed in 63% of patients in controlled trial; adjust dose for renal insufficiency; consider use of G-CSF if continued therapy desired in the setting of neutropenia |
| Valganciclovir | Congenital CMV infection | 32 mg/kg per day divided twice daily; a controlled clinical trial of 6 months' oral suppression in infants with symptomatic congenital CMV infection demonstrated improved hearing and neurodevelopmental outcomes | Valine ester (prodrug) of ganciclovir; toxicity profile similar to that of ganciclovir; long-term suppressive therapy not well studied in infants; theoretical concerns of carcinogenesis, gonadal toxicity |
| Lamivudine | Hepatitis B, HIV infection | For children aged 3 months to 16 years, the recommended dosage is 4 mg/kg, up to 150 mg per dose, twice daily. | Chronic hepatitis B; also used for HIV therapy |
| Tenofovir | Hepatitis B, HIV infection | For children aged ≥12 years and weighing >35 kg, the recommended dosage is 300 mg daily. | Chronic hepatitis B |
| Entecavir | Hepatitis B | For therapy-naïve children older than 2 years and weighing >10 kg, the recommended dosages are 0.15 mg orally once a day for weight 10 to 11 kg, 0.2 mg orally once a day for weight >11 to 14 kg, 0.25 mg orally once a day for weight >14 to 17 kg, 0.3 mg orally once a day for weight >17 to 20 kg, 0.35 mg orally once a day for weight >20 to 23 kg, 0.4 mg orally once a day for weight >23 to 26 kg, 0.45 mg orally once a day for weight >26 to 30 kg, and 0.5 mg orally once a day for weight >30 kg. For children older than 2 years and weighing >10 kg who have previously received lamivudine the dosages are 0.3 mg orally once a day for weight 10 to 11 kg, 0.4 mg orally once a day for weight >11 to 14 kg, 0.5 mg orally once a day for weight >14 to 17 kg, 0.6 mg orally once a day for weight >17 to 20 kg, 0.7 mg orally once a day for weight >20 to 23 kg, 0.8 mg orally once a day for weight >23 to 26 kg, 0.9 mg orally once a day for weight >26 to 30 kg, and 1 mg orally once a day for weight >30 kg. | Chronic hepatitis B. Adjust dose for renal insufficiency |

**TABLE
37.2****Antiviral Agents Commonly Used in Neonatology Practice—cont'd**

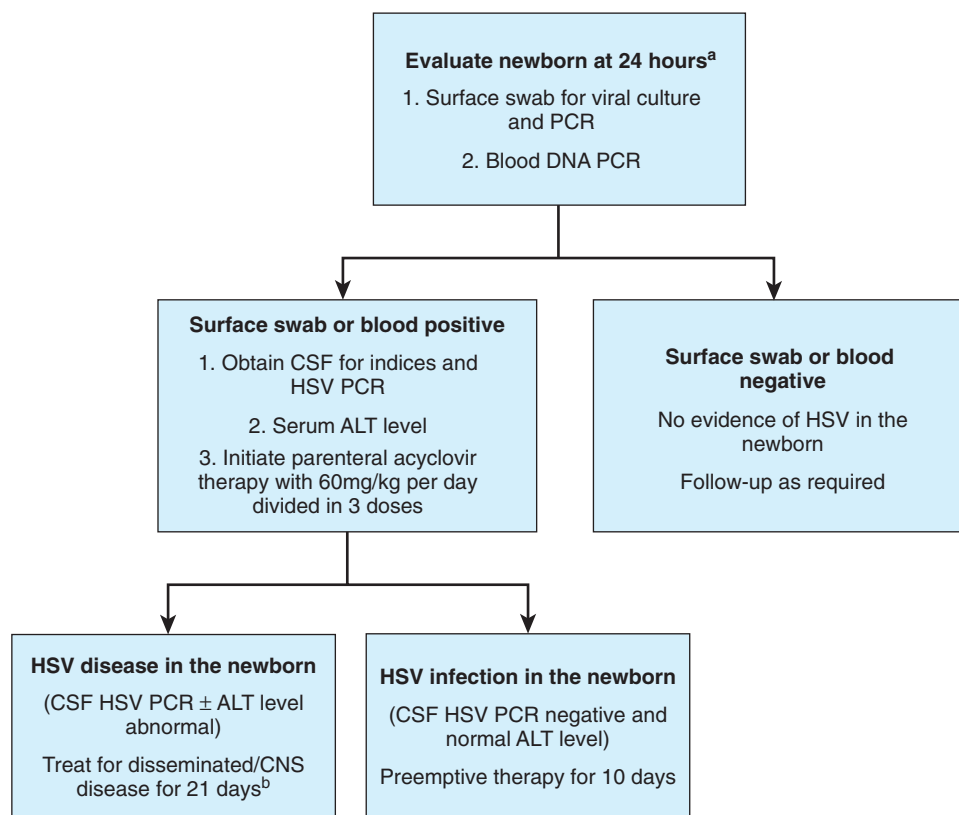

| Antiviral Agent | Indication | Dose, Route of Administration, Duration of Therapy | Comments |
|------------------------------|--|--|--|
| Interferon alfa-2b | Hepatitis B, hepatitis C | 3 million to 6 million international units per square meter three times per week; up to 24 months' duration; combined with oral ribavirin therapy for hepatitis C | Chronic hepatitis B; no data in neonates; chronic hepatitis C when administered with ribavirin; systemic side effects (fever, flulike symptoms, anorexia); leukopenia; thyroid autoantibodies |
| Pegylated interferon alfa-2b | Hepatitis B, hepatitis C | 1.5 µg/kg once per week; no information on dosing in children aged <2 years | Chronic hepatitis B; administer in conjunction with ribavirin for hepatitis C; systemic side effects (fever, flulike symptoms, anorexia); leukopenia; thyroid autoantibodies; side effects less common with pegylated formulations |
| Adefovir | Hepatitis B | Not recommended in children aged <10 years; 0.3 mg/kg orally once daily in children aged 2 to 6 years has favorable pharmacokinetics | Chronic hepatitis B; no safety or efficacy data in infants or young children |
| Ribavirin (oral) | Hepatitis C | 15 mg/kg per day orally; no information on dosing in children aged <2 years | Hemolytic anemia; teratogenic in animal models |
| Ribavirin (aerosol) | Respiratory syncytial virus infection | Standard ribavirin aerosol therapy is 6 g per 300 mL water for 18 h daily; short-duration therapy, 6 g per 100 mL water given for 2 h three times per day | Not indicated for use with mechanical ventilator; conjunctivitis; bronchospasm |
| Oseltamivir | Influenza A virus infection, influenza B virus infection | For children weighing <15 kg, the recommended dosage is 30 mg orally twice daily for 5 days (treatment) or 10 days (prophylaxis) | Not typically recommended in children aged <1 year; FDA-approved guidelines for emergency use of oseltamivir in pediatric patients younger than 1 year in 2009 in response to H1N1 influenza pandemic |
| Zanamivir | Influenza A virus infection, influenza B virus infection | Recommended dosage of zanamivir for treatment of influenza is two inhalations (one 5-mg blister per inhalation for a total dose of 10 mg) twice daily (approximately 12 h apart) | Not recommended in children aged <5 years |

CBC, Complete blood cell count; *CMV*, cytomegalovirus; *CNS*, central nervous system; *FDA*, Food and Drug Administration; *G-CSF*, granulocyte colony-stimulating factor; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *SEM*, skin, eye, or mucous membranes; *VarizIG*, varicella-zoster immunoglobulin; *VZV*, varicella-zoster virus.

therapy (80% die), and most survivors have serious neurologic sequelae (Whitley, 1988; Thompson and Whitley, 2011). IV antiviral therapy has decreased disseminated disease mortality to approximately 30%, and approximately 80% of surviving infants have a normal neurologic outcome (Corey and Wald, 2009). Antiviral therapy has decreased neonatal CNS infection mortality from approximately 50% to 6%, but more than 70% of survivors have sequelae (Freij and Sever, 1988; Engman et al., 2008; Corey and Wald, 2009). Lethargy at initiation of therapy has been associated with a higher mortality rate in neonates with disseminated HSV infection (Kimberlin et al., 2001). Infants with skin involvement often have recurrent crops of skin vesicles for several years. In an infant younger than 6 months, readmission to the hospital for evaluation and IV acyclovir is appropriate when cutaneous recurrences are observed.

Treatment of asymptomatic neonates potentially exposed to HSV in the birth canal is controversial. This situation sometimes arises when a maternal perineal lesion is discovered after vaginal delivery. Some experts have in the past recommended neonatal surface cultures and administration of prophylactic antivirals, but there has little evidence to support this approach. A recent set of

guidelines endorsed by the AAP provided evidence-based guidance on the treatment of neonates born to women with active genital herpetic lesions (Kimberlin et al., 2013; Pinninti and Kimberlin, 2014). These guidelines are predicated on the availability of type-specific PCR and serology for HSV and emphasize that decision making should be predicated on the nature of the maternal infection (primary versus nonprimary) and the results of diagnostic virology evaluation of the newborn using samples obtained at 24 hours of age. For treatment of newborns born to women with HSV genital lesions at delivery and a history of genital herpes, careful coordination between the pediatric and obstetric teams is required, and maternal PCR and culture of suspect lesions coupled with serologic assessment are required, along with virologic testing of the newborn at 24 hours of age. These recommendations are summarized in Fig. 37.3 and are applicable to infants born by caesarean delivery or by the vaginal route. For infants born to women with lesions at delivery and no history of genital herpes before pregnancy, it is recommended that maternal PCR and culture of vaginal lesions be performed (both to identify and to type HSV) and that the newborn be evaluated at 24 hours of age by obtaining surface swabs for culture and PCR, blood for HSV PCR, CSF for HSV

^aWaiting for 24 hours after delivery is recommended to differentiate contamination of neonatal skin by maternal secretions versus true HSV infection of the baby.

^bAfter completion of parenteral therapy, treat with oral acyclovir suppressive therapy for 6 months (300mg/m² per dose three times per day).

• **Fig. 37.3** Treatment of a newborn born to a woman with presumed active genital herpes simplex virus (HSV) lesions at delivery in the setting of recurrent genital HSV infection. A waiting period of 24 hours is currently recommended in this setting before surface cultures are obtained and polymerase chain reaction (PCR) for HSV genome detection (and blood for HSV PCR) from the neonate. This approach aids in differentiation of contamination of neonatal skin from maternal secretions from true infection of the newborn. ALT, Alanine aminotransferase; CSF, cerebrospinal fluid.

PCR, and serum alanine aminotransferase (ALT) level and that parenteral acyclovir therapy (60 mg/kg per day in three divided doses) be commenced. The duration of therapy is then dictated by the results of the diagnostic evaluation. For infants born in settings where PCR and type-specific serology may not be readily available, the most important variable informing clinical management is the maternal history. Infants born to women with primary, first-episode genital HSV infection have an up to approximately 60% risk of neonatal HSV infection (Brown et al., 2003). On the other hand, term infants exposed to HSV in the birth canal and born to women with long-standing histories of recurrent genital herpes are at low risk (<1%) of infection, and if the infant is asymptomatic, observation without antiviral therapy is sufficient. If the maternal HSV history is unclear, the infant is premature, or other obstetric complications or risk factors are present (e.g., prolonged rupture of membranes, maternal fever, signs or symptoms of chorioamnionitis, fetal scalp electrode monitoring), then empiric antiviral therapy is warranted. In settings where PCR and type-specific serology may not be readily available, after the appropriate specimens have been collected and sent for virologic analysis, the infant should receive parenteral acyclovir therapy (60 mg/kg per day) pending the results of diagnostic virology studies.

Similarly controversial is the question of whether empiric acyclovir therapy should be administered to neonates who are admitted for evaluation of febrile illnesses in the first 30 days of life, the so-called rule-out sepsis evaluation. Standard practice in most children's hospitals is to rule out sepsis in this setting by administration of broad-spectrum antibiotics pending the result of diagnostic cultures of blood, urine, and CSF. Some experts recommend the use of empiric acyclovir therapy in this setting (Long, 2008), citing data that indicate that the prevalence of neonatal HSV infection is similar to that of invasive bacterial infection in this setting and that infants may exhibit fever and sepsis-like syndrome as the only manifestations of HSV infection (Caviness et al., 2008b). Other experts recommend a more selective approach, based on analysis of history, risk factors, and laboratory and radiographic analyses, such as liver function tests and chest radiograph (Kimberlin, 2008; Gaensbauer et al., 2014). A retrospective analysis of an empiric acyclovir strategy restricted to newborns with onset of febrile illness at 21 days of age or earlier, who would typically receive empiric parenteral antibiotic therapy, captured 90% of HSV cases and anticipated a rate of HSV CNS infection similar to that of bacterial meningitis (Long et al., 2011). An estimated 1.3% of empirically treated patients in this study had

HSV infection. Another study, of 49 infants evaluated for fever at less than 42 days of age, observed that most of the infants with documented HSV infection (84%) had seizure, vesicular rash, or a critical level of illness. A subset of patients (16%) lacked classic signs at hospitalization; most manifested signs suggestive of HSV within 24 hours (Curfman et al., 2016).

In addition to its critical role in the management of the acute clinical syndromes of neonatal HSV infection, acyclovir may be of benefit when administered as long-term suppressive therapy in the first 6 months of life. The Collaborative Antiviral Study Group (CASG) has reported results of controlled studies evaluating long-term oral suppressive acyclovir therapy after neonatal HSV infection aimed at prevention of both recurrent skin lesions and neurologic sequelae. The observation driving this study is that recurrent skin lesions (more than three episodes) within the first 6 months of life predict an adverse neurologic prognosis, possibly because recurrent skin lesions are a surrogate marker for subclinical reactivation events in the CNS (Whitley, 1991). Phase I and phase II trials demonstrated fewer cutaneous recurrences in the treatment group but did not have enough participants to analyze the effect on neurologic outcomes (Kimberlin et al., 1996a). These observations supported the hypothesis that reduction of cutaneous recurrences in the first year of life could result in improved neurodevelopmental outcome (Gutierrez and Arvin, 2003). That long-term oral suppressive therapy may be beneficial for improving long-term neurodevelopmental outcomes with regard to neonatal HSV infection was suggested by a 2-year pilot study of oral suppressive therapy in a cohort of 16 infants (Tiffany et al., 2005). In this uncontrolled study, all children were independently mobile, free of seizures, and had normal vision and speech development at the time of final neurodevelopmental assessment. A phase III, placebo-controlled trial performed by the CASG confirmed that acyclovir suppressive therapy for 6 months after completion of IV therapy for neonatal HSV disease resulted in improved neurodevelopmental outcomes (Kimberlin et al., 2011). Infants with CNS disease randomized to receive oral acyclovir therapy had improved neurodevelopmental outcome and fewer frequent recurrences of skin lesions while receiving therapy. The results of this study have led to a recommendation that infants with neonatal HSV infection of any disease classification should receive oral acyclovir therapy (recommended dosage regimen 300 mg/m² per dose, three times a day) for 6 months. Absolute neutrophil counts should be monitored at 2 and 4 weeks, and monthly thereafter, after commencement of suppressive therapy (Pinninti and Kimberlin, 2014). The emergence of acyclovir-resistant HSV strains is a concern, both during treatment for the acute episode of neonatal infection and in infants receiving long-term suppressive therapy (Kimberlin et al., 1996b; Oram et al., 2000; Levin et al., 2001; Kakiuchi et al., 2013; Bache et al., 2014). More data are needed on the long-term risks of antiviral resistance and on novel treatment alternatives (Birkmann and Zimmermann, 2016). In contrast, no long-term benefit of suppressive nucleoside therapy was noted in adult survivors of HSV encephalitis (Gnann et al., 2015).

Prospects for Prevention

Recent developments focused on preventing HSV infections among women of childbearing age include consideration of maternal screening programs and the use of antiviral agents in women at risk of transmission of infection. The availability of reliable kits that allow specific serodiagnosis of HSV-1 and HSV-2 infections has enabled the identification of asymptomatic women with genital herpes who can be counseled appropriately during pregnancy

(Sauerbrei and Wutzler, 2007). Although routine seroscreening of pregnant women is not currently considered a standard of care, screening in some instances, including situations where high maternal anxiety exists, seems justified. There is no evidence that routine administration of suppressive antivirals during pregnancy can improve outcomes or reduce disease in newborns (Sheffield et al., 2006), although this approach has become common in many obstetric practices (Hollier and Wendel, 2008). One benefit of suppressive antiviral therapy during pregnancy for a woman with a history of genital herpes may be a reduced likelihood of caesarean delivery (Brown et al., 2003; Hollier and Wendel, 2008). It is important to recognize that transmission of virus and subsequent symptomatic neonatal HSV infections have been described even in the face of maternal suppressive therapy with antivirals (Pinninti et al., 2012). Strategies for preventing neonatal herpes can also target prevention of intrapartum transmission by caesarean delivery. If a mother has active genital HSV infection at the time of delivery, and if the membranes are intact or have been ruptured for less than 4 hours, both the AAP and the American College of Obstetricians and Gynecologists recommend caesarean delivery. The role of intrapartum antiviral therapy or IVIG has not been studied in this setting.

Even with careful histories and meticulous physical examination during labor and delivery, many at-risk deliveries cannot be predicted or identified, because so many HSV-2-seropositive women are asymptomatic, do not know that they have genital herpes, and may unknowingly shed virus at the time of delivery. Infants in whom HSV infection is known or highly suspected should be isolated with contact precautions, and skin lesions should be covered. Finally, any healthcare provider with active herpetic whitlow or other skin lesions should not have direct patient care responsibilities for neonates.

Several phase I, II, and III clinical trials of HSV vaccines are ongoing (Stanberry and Rosenthal, 2005). A vaccine that prevented genital HSV infection, or reduced HSV shedding, would in principle reduce the incidence of neonatal HSV infection. A double-blind, randomized trial of an HSV-2 glycoprotein D subunit vaccine given with alum adjuvant and 3-O-deacylated monophosphoryl lipid A was reported in a study of individuals whose regular sexual partners had a history of genital herpes. The vaccine was efficacious in women who were seronegative for both HSV-1 and HSV-2, but it was not efficacious in women who were seropositive for HSV-1 and seronegative for HSV-2 at the baseline. The vaccine had no efficacy in men, regardless of serostatus (Stanberry et al., 2002). Other live-attenuated and subunit HSV vaccines are currently in development (Iwasaki, 2016; Johnston et al., 2016).

Varicella–Zoster Virus

VZV is a member of the α -herpesvirus subfamily of the *Herpesviridae*. Like the related HSV-1 and HSV-2, VZV can infect neurons, where it establishes latent infection. Primary varicella infection, commonly known as *chickenpox*, usually results in a fever and a characteristic vesicular exanthem. The illness often includes other systemic symptoms, such as headache and malaise. Reactivation from latency, which can occur years or decades after the primary VZV infection, is usually referred to as *zoster* or *shingles*. Zoster is characterized by a painful vesicular rash in a dermatomal distribution and in older patients can lead to postherpetic neuralgia.

The neonatologist may encounter consequences of maternal VZV infection in two different clinical presentations. In *congenital* varicella, VZV is transmitted to the fetus in the first or second

trimester of pregnancy, where it can produce a number of teratogenic consequences (Laforet and Lynch, 1947; Sraubstein et al., 1974; Auriti et al., 2009; Smith and Arvin, 2009). In contrast, *neonatal* varicella occurs in the setting of primary maternal varicella acquired late in the third trimester, and the affected infant can exhibit symptoms and signs in the neonatal period. This section reviews both of these presentations of VZV-related disease in infants.

Epidemiology of Maternal and Perinatal Varicella–Zoster Virus Infection

Before the advent of routine childhood vaccination against chickenpox, it was estimated that the VZV seroprevalence in women of childbearing age was greater than 95%, because of the formerly ubiquitous nature of this infection. In this era, primary VZV infections during pregnancy occurred with a frequency of 5 to 7 per 10,000 pregnancies in the United States (Balducci et al., 1992; Brunell, 1992). The major concern in the setting of primary maternal VZV infection is the risk of congenital varicella syndrome (CVS). For pregnant women with primary varicella infection, the rate of transmission to the fetus is estimated to be approximately 25%. Only a subset of infected fetuses exhibit symptomatic disease. Approximately 130 cases of CVS were reported in the literature between 1947 and 2013 (Sauerbrei and Wutzler, 2000; Ahn et al., 2016). The risk of symptomatic intrauterine VZV infection after maternal varicella occurring during the first 20 weeks of pregnancy is approximately 1%–2% (Siegel, 1973; Paryani and Arvin, 1986; Enders et al., 1994; Pastuszak et al., 1994). In a systematic review the estimated incidence of CVS was 0.59% for women infected with VZV during the entire pregnancy and 0.84% for those infected during the first 20 weeks of pregnancy (Ahn et al., 2016). Other smaller case series have found fetal infection rates in the range of 0.8% in women with primary infections (varicella-like rash and positive immunoglobulin M [IgM] serologic findings; Sanchez et al., 2011). Symptomatic disease appears to be more common in female infants (Sauerbrei and Wutzler, 2000). CVS has been reported in two pregnancies following maternal zoster (Ahn et al., 2016), although this is very rare insofar as a prospective study of infants born to 366 mothers with a clinical history of zoster during pregnancy found no infants with CVS (Enders et al., 1994).

Maternal infection in the third trimester is not associated with CVS, presumably because this falls outside the time frame when VZV is teratogenic to the developing fetus. Maternal infection just before or after delivery poses a high risk of neonatal varicella. Before the advent of VZV vaccination, neonatal varicella was encountered much more commonly than CVS. For infants in whom maternal illness begins 5 days or less before delivery or up to 2 days after delivery, the infant attack rate is 17%–31% (Meyers, 1974; Feldman, 1986; Brunell, 1992). Because the incubation period for varicella is between 10 and 21 days, cases beginning in the first 10 days of life are considered to have been acquired in utero.

Pathogenesis and Clinical Manifestations

CVS is acquired from a maternal primary varicella infection that occurs during the first or second trimester. The virus is thought to be transmitted transplacentally during the viremia that precedes or accompanies the rash of chickenpox. Ascending infection from cervical infection has been proposed as a potential mechanism of transmission but is probably much less common (Sauerbrei and Wutzler, 2000). It has been proposed that some of the congenital malformations associated with CVS may be a consequence of zoster-like virus reactivation events in the infected fetus rather

than the direct effects of the primary viral infection. This explanation is supported by the common finding of unusual cicatricial rashes in dermatomal distributions (more compatible with zosteriform reactivation events than primary skin infection) in newborns with CVS. Other clinical manifestations include asymmetric muscular atrophy with limb hypoplasia, low birth weight, neurologic abnormalities (cortical or spinal cord atrophy, seizures, microcephaly, encephalitis, Horner syndrome), and ophthalmologic abnormalities (chorioretinitis, microphthalmia, atrophy, and cataracts; Brunell, 1992; Feldman, 1986; Sauerbrei and Wutzler, 2000). Gastrointestinal (GI) abnormalities are reported in 15%–23% of cases; findings include duodenal stenosis, dilated jejunum, small descending colon, intestinal atresia or bands, and hepatic calcifications (Alkalay et al., 1987; Jones et al., 1994). Immature fetal cell-mediated immune response may explain the short latency period and the inadequate protection from the consequences of episodes of reactivation in utero (Higa et al., 1987; Kustermann et al., 1996). Pathology reports have noted destruction of neural tissue with residual dystrophic calcifications, chronic active inflammation in nonneural tissues surrounding viral inclusions, and evidence of chronic placental villitis (Qureshi and Jacques, 1996; Bruder et al., 2000; Petignat et al., 2001).

Maternal varicella near term or immediately postpartum can lead to neonatal varicella. Neonatal varicella is usually caused by maternal chickenpox acquired during the last 3 weeks of pregnancy. Infection may be transmitted perinatally by transplacental viremia (most cases) or by ascending infection from the birth canal; it can also be contracted postnatally by the aerosol route or by direct contact with infectious lesions. Serious postnatal infection acquired from maternal varicella via breastfeeding has not been reported. Neonatal varicella may develop despite the administration of varicella–zoster immunoglobulin (VariZIG) to the infant at birth. Transplacentally transmitted infections occur in the first 10 to 12 days of life, whereas chickenpox after that time is most likely acquired by postnatal infection. The clinical presentation differs markedly for cases in which maternal rash began 5 days or more before delivery from those in which maternal illness occurred from 5 days before to 2 days after delivery. When maternal varicella is noted more than 5 days before delivery, neonatal disease usually begins within the first 4 days of life and is typically mild. In contrast, neonatal varicella in a newborn whose mother develops varicella from 5 days before until 2 days after delivery has a high risk of morbidity and mortality (Isaacs, 2000; Tan and Koren, 2006). In this second group, neonatal disease typically begins between 5 and 10 days after delivery, and a fatal outcome has been reported in 23%–30% of cases (Brunell, 1966; Sauerbrei and Wutzler, 2001). When the disease appears in this setting, it closely resembles varicella in the immunodeficient or immunosuppressed host. Recurrent crops of skin vesicles develop over a prolonged period. Typical presenting signs are fever, hemorrhagic rash, and visceral dissemination with involvement of the liver, lung, and brain. Secondary bacterial infection may occur.

Prospective studies of the long-term outcomes of CVS have not been performed, and there is probably a wide continuum of disease. Among the 96 infants reviewed by Sauerbrei and Wutzler (2000), 14 (15%) had clinical signs of zoster during early infancy; these infants had been exposed to varicella between 8 and 24 weeks' gestation. Some experts consider early zoster infections as one criterion for diagnosis of CVS. Between 1% and 2% of infants without clinical evidence of CVS but whose mothers had chickenpox in the second and third trimesters develop zoster in the first few weeks of life; if this occurs, consideration should be given to

ophthalmologic evaluations to rule out the possibility of CVS (Sauerbrei and Wutzler, 2000; Enders et al., 2004). Overall mortality rates for CVS are estimated at 30%. Deaths occur in the first few months of life, usually secondary to severe pulmonary disease (Pastuszak et al., 1994; Sauerbrei and Wutzler, 2000).

Diagnostic Studies

Prenatal diagnosis—by means of quantification of varicella-specific IgM on fetal blood obtained by cordocentesis or through PCR analysis of chorionic villi, fetal blood, and amniotic fluid—has been attempted (Cuthbertson et al., 1987; Kustermann et al., 1996; Mouly et al., 1997). Although the yield of PCR on amniotic fluid or fetal blood is higher than that of serologic analysis of fetal IgM or viral cultures, large prospective studies of the correlation of such findings with clinical outcomes have not been performed. Reported prenatal ultrasonographic findings include polyhydramnios, hydrops, progressive IUGR, microcephaly, limb hypoplasia, and liver hyperechogenicities (Pretorius et al., 1992; Petignat et al., 2001). Abnormal ultrasonographic findings might not develop in a fetus for at least 5 weeks after maternal infection (Kerkering, 2001).

Serologic studies can be performed postnatally on infants (Paryani and Arvin, 1986). Suspected congenital infection with varicella can be confirmed by the finding of persistent VZV IgG beyond the presumed duration of passive transfer of maternal antibodies (at least 6 to 7 months). Detection of fetal IgM can also confirm infection, but it is less useful because only one-fourth of infants reported with classic CVS have positive VZV IgM titer test results (Enders et al., 1994; Sauerbrei and Wutzler, 2000). Highly sensitive direct fluorescent antibody (DFA) tests are available and demonstrate high levels of sensitivity and specificity (Coffin and Hodinka, 1995; Chan et al., 2001). VZV can also be detected from skin lesions by PCR (Leung et al., 2010). DFA and PCR are often extremely low yield in infants with suspected congenital infection compared with infants and children who have acquired varicella infections. Neuroradiographic demonstration of intracranial calcifications has been reported with CVS, but this is not a common finding (Kerkering, 2001).

Treatment

No controlled studies examining the effect of antiviral therapy to prevent or treat CVS have been conducted. Some experts have recommended oral acyclovir therapy for pregnant women with varicella, especially during the second and third trimesters (American Academy of Pediatrics Committee on Infectious Diseases, 2015). IV treatment with acyclovir for the infected pregnant woman is recommended for patients with serious complications of varicella, particularly pneumonia. Anecdotal observations suggest a potential effect of acyclovir on the progression of eye disease in CVS (Sauerbrei and Wutzler, 2000). However there are no recommendations for the use of acyclovir or IVIG for treatment or prevention of CVS. For neonatal varicella, treatment with IV acyclovir, 60 mg/kg per day divided into doses every 8 hours, is recommended, particularly for infants at the highest risk of adverse outcomes (i.e., the infant born to a woman who develops varicella from 5 days before until 2 days after delivery; Table 37.2).

Prevention

Women who develop VZV infection in pregnancy should be informed of the potential adverse maternal and fetal sequelae, the risk of transmission to the fetus, the options available for prenatal diagnosis, and potential therapies (Shrim et al., 2012). Treatment of a pregnant patient following exposure to VZV or on the

• BOX 37.3 Candidates for Varicella–Zoster Immunoglobulin After Significant Exposure to Varicella–Zoster Virus Infection in Perinatology and Neonatology Practice

- Pregnant women without evidence of immunity
- Newborn whose mother develops chickenpox within 5 days before delivery or within 48 hours after delivery
- Hospitalized premature infant (≥28 weeks' gestational age) whose mother has no history of chickenpox or serologic evidence of prior infection
- Hospitalized preterm infants (<28 weeks' gestational age or birthweight ≤1000 g) regardless of the maternal history of varicella or varicella–zoster virus serostatus

development of an illness compatible with a primary VZV infection is challenging (Benoit et al., 2015). In late 2012, VariZIG was approved by the Food and Drug Administration (FDA) for postexposure prophylaxis of varicella for individuals at high risk of severe disease (Centers for Disease Control and Prevention, 2013). If a susceptible pregnant woman has a significant exposure to varicella, administration of VariZIG to her and her newborn should be considered. These recommendations are summarized in Box 37.3. Pregnant patients who lack a history of VZV infection should receive VariZIG as soon as possible following VZV exposure, up to 10 days but ideally within 96 hours of exposure, for the greatest effectiveness (Bapat and Koren, 2013). Newborns of mothers in whom varicella develops from 5 days before to 2 days after delivery should receive VariZIG as soon as possible. VariZIG is given intramuscularly at a recommended dose of 125 units per 10-kg bodyweight, up to a maximum of 625 units. If VariZIG is unavailable, IVIG (400 mg/kg) can be a substitute. Passive immunoprophylaxis has been shown to prevent chickenpox in exposed older children (Brunell et al., 1969) but does not always prevent neonatal disease (Reynolds et al., 1999). Approximately 50% of exposed infants treated with immunoglobulin can still develop varicella, but the disease is often attenuated, and approximately 10% have severe disease (Hanngren et al., 1985). For healthy term newborns exposed postnatally to varicella, including newborns whose mother's rash began more than 48 hours after delivery, VariZIG is not generally indicated. VariZIG is not indicated for an infant whose mother has zoster. Breastfeeding is not contraindicated in newborns born to women with VZV infection.

Follow-up of infants exposed to VZV and treated with VariZIG can include consideration of serologic testing (enzyme immunoassay, latex agglutination, or indirect fluorescent antibody staining for IgG) to determine whether asymptomatic infection has elicited immune protection. Some experts recommend repeated administration of VariZIG after a repeated exposure of an infant in whom varicella did not develop more than 3 weeks after administration of the initial dose of VariZIG, although the risk to these infants is less well defined. Infants receiving VariZIG should also be placed in respiratory isolation for 28 days or until discharge, because administration of VariZIG can prolong the incubation period.

In the event of a significant varicella exposure in a newborn nursery, infants whose mothers have no history of chickenpox and who have undetectable antivariella antibody titers should be considered candidates for VariZIG. All exposed infants of less than 28 weeks' gestational age or with birthweights less than 1000 g,

regardless of maternal history, should receive VariZIG (Box 37.3). The decision to use VariZIG in the premature infant older than 28 weeks' gestation should be predicated on maternal history of chickenpox or serologic evidence of protection.

Acyclovir has also been recommended by some experts for postexposure prophylaxis in the setting of a nursery outbreak of VZV infection (Hayakawa et al., 2003; Shinjoh and Takahashi, 2009). A suggested dosage is 10 mg/kg by mouth four times per day for 7 days. All exposed healthcare professionals without evidence of immunity should be excused from patient contact from day 8 to day 21 after exposure to an infectious patient or to day 28 if the individual has received VariZIG (American Academy of Pediatrics Committee on Infectious Diseases, 2015).

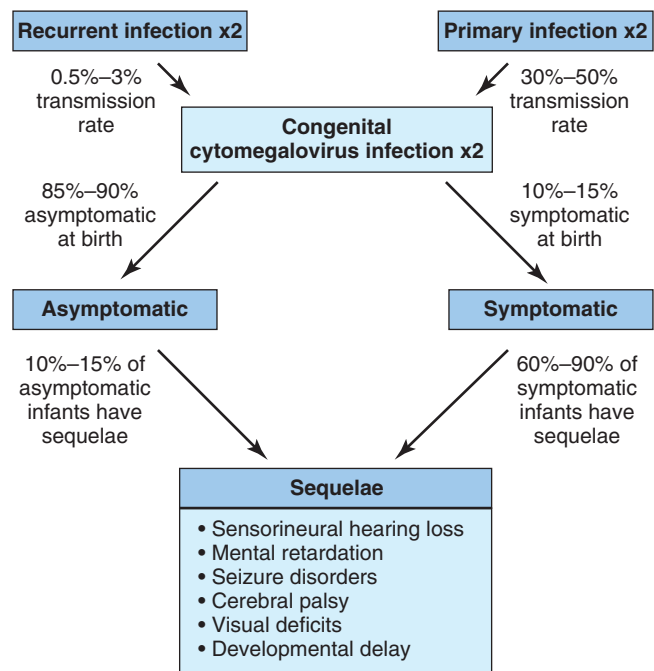

The best means of prevention is to follow current recommendations for universal varicella immunization of all children at 12 to 15 months of age, as well as vaccination of all susceptible adolescents and adults. VZV vaccines have been licensed in three formulations: a monovalent formulation for children and young adults, a combination vaccine given with the measles–mumps–rubella vaccine in children and young adults (not currently manufactured), and a monovalent formulation for adults older than 60 years for prevention of herpes zoster (shingles). There is no evidence that CVS occurs after exposure to varicella vaccine during pregnancy. From March 17, 1995, through March 16, 2005, 981 women were enrolled in a pregnancy registry for women exposed to varicella vaccine (Shields et al., 2001; Wilson et al., 2008; Marin et al., 2014). Pregnancy outcomes were available for 629 prospectively enrolled women. Among the 131 live births to VZV-seronegative women, there was no evidence of CVS. Nonetheless it is recommended that adolescents and women of childbearing age should avoid pregnancy for at least 1 month after immunization.

Cytomegalovirus

CMV infection is ubiquitous in the general population and generally produces few if any symptoms in the immunocompetent infant, child, or adult. The mild nature of primary infection in most individuals belies the severe nature of CMV-induced illness in those with impaired, suppressed, or immature immune systems, including infected newborns. Among the perinatally acquired viral infections in the developed world, CMV infection imposes the largest economic burden and produces the greatest long-term neurodevelopmental morbidity.

Epidemiology

In retrospect, the first description of congenital CMV disease was in 1904, when Ribbert (1904) observed the large inclusion-bearing cells that represent the typical histopathologic finding of CMV end-organ disease in a stillborn infant. In 1920 a viral cause was proposed for the “cytomegaly” seen in tissue sections of these inclusion-bearing cells (Goodpasture and Talbot, 1921), and it would be several more decades before the ubiquitous nature of this virus and the depth and breadth of the disease it produces would be elucidated. In the developed world, CMV transmission occurs in 0.5%–2% of all live births, making CMV infection the most common congenital viral infection (Demmler, 1991; Kenneson and Cannon, 2007; Sharon and Schleiss, 2007; Manicklal et al., 2013; Swanson and Schleiss, 2013; Lanzieri et al., 2014). Approximately 40,000 neonates are born with CMV infection every year in the United States. Consequently, congenital CMV infection has a much greater impact than other more commonly recognized causes of birth defects in newborns. More than 8000 children per

• **Fig. 37.4** Profiles of congenital cytomegalovirus (CMV) epidemiology, infection, and outcome. The rates of transmission to the fetus are highest in the setting of primary maternal infection (up to 50%), although 0.5%–3% of women with preconception immunity may nonetheless transmit CMV because of reinfection or reactivation of latent infection. Among all infants with congenital CMV infection, regardless of maternal immune status during pregnancy, approximately 10%–15% have symptoms or signs at birth (e.g., microcephaly, chorioretinitis, hepatosplenomegaly, petechiae, purpura, thrombocytopenia, hepatitis, seizures, pneumonitis). Symptomatic infants have the highest risk of neurodevelopmental sequelae, although any infant with congenital CMV infection is potentially at risk of sequelae. Among asymptomatic congenitally infected infants with sequelae, the most common manifestation is sensorineural hearing loss, which may not be present at birth.

year will be permanently disabled by congenital CMV infection (Fig. 37.4). This number is higher than the number affected by other, better known childhood conditions such as Down syndrome, fetal alcohol syndrome, and spina bifida (Ross et al., 2006; Cannon et al., 2012). Rates of congenital CMV infection tend to parallel those of maternal seropositivity (Britt, 2015) and differ substantially across populations (Mustakangas et al., 2000; Manicklal et al., 2013). Although the lifetime risk of acquiring CMV infection is high, approaching 90% by the eighth decade of life (Staras et al., 2006), seroprevalence is substantially lower among women of childbearing age. Seronegative women are therefore at risk of acquiring primary infections during pregnancy. Primary infections pose an increased risk of transmission to the fetus and possibly a higher risk of sequelae. Every year in the United States, approximately 27,000 seronegative women acquire a primary CMV infection (Colugnati et al., 2007). Among pregnant women, the overall estimated annual seroconversion rate in the United States is 2.3% (Hyde et al., 2010).

Seroprevalence rates for CMV differ significantly globally and are generally inversely correlated with socioeconomic status. CMV seroprevalence is greater in childhood in developing countries. In developed countries, seroprevalence tends to be higher in blacks and Hispanics, low-income groups, and individuals without higher

education. Young maternal age, single marital status, and nonwhite race are associated with higher rates of congenital CMV infection. Women with increased occupational exposure to young children (including day care providers) are at elevated risk of acquisition of primary CMV infections (Pass et al., 1986; Adler, 1989; Pass et al., 1990; Stagno and Cloud, 1994; Hyde et al., 2010). Healthcare providers in contrast are not at increased risk of acquisition of a primary CMV infection (Dworsky et al., 1983).

Pathogenesis

Morphologically and at the genome level, CMV has the largest genome of any human pathogen (Boeckh and Geballe, 2011). There are approximately 160 known CMV genes, although on the basis of its coding potential, CMV has the potential to encode more than 250 open reading frames. The mechanisms by which CMV injures the fetus involve a complex interplay of viral gene products, maternal immune response, and placental biology. CMV encodes genes modifying the cell cycle, cellular apoptosis mechanisms, inflammatory responses, and evasion of host immune responses. The pathogenesis of disease associated with acute CMV infection has been attributed to lytic virus replication, with end-organ damage occurring either secondary to virus-mediated cell death or from pathologic host immune responses targeting virus-infected cells (Britt, 2008; Schleiss, 2011). The factors that contribute to fetal injury include the timing of infection relative to the gestational age of the fetus (Pass et al., 2006), the maternal immune status (Fowler et al., 1992), the extent of associated placental injury (Fisher et al., 2000), the magnitude of the viral load in the amniotic fluid (Lazzarotto et al., 2000), the induction of host genes occurring in response to infection (Challacombe et al., 2004), and possibly the genotype of the particular strain of CMV infecting the fetus (Arav-Boger et al., 2006; Arav-Boger, 2015). The relative contribution of maternal, placental, and fetal compartments in the pathogenesis of disease remains incompletely defined. Much of the injury that CMV produces in the newborn may be caused by placental insufficiency and not by viral infection of the fetus (Schleiss, 2006a). Delivery of oxygen, substrate, and nutritional factors to the fetus is impaired for a CMV-infected placenta. Moreover, CMV infection of the placenta might contribute to IUGR and fetal injury via induction of proinflammatory cytokines and modulation of normal trophoblast gene expression (Yamamoto-Tabata et al., 2004; Chan and Guilbert, 2005; Chou et al., 2006; La Torre et al., 2006; Maidji et al., 2007). Identified as a site for major pathogenic virus-induced injury, the placenta is increasingly considered to be a target for novel therapeutic interventions, such as CMV hyperimmune globulin for women with primary CMV infection during pregnancy (La Torre et al., 2006; Adler and Nigro, 2013; Adler, 2015).

Congenital CMV infection leads to more severe disease and an increased risk of sequelae in the setting of primary maternal infection during pregnancy. Primary maternal infection confers a 40%–50% risk of intrauterine transmission during gestation, versus the 0.5%–2% transmission risk in women with preconceptional immunity (Fowler et al., 2003). Although preconception immunity confers some level of protection for the fetus, congenital infection in immune women can lead to symptomatic disease and sequelae. Congenital CMV infection in previously immune mothers appears to be related to reinfection with new strains of virus, with variations in epitopes of virally encoded proteins that may correlate with decreased maternal immunity (Boppana et al., 1999, 2001; Ross et al., 2010; Yamamoto et al., 2010). Many of the pathologic manifestations of congenital CMV infection that reflect visceral

organ involvement (hepatitis and pneumonitis) are also observed in immunocompromised adults with disseminated CMV disease. The developing fetal brain is also highly susceptible to CMV-induced injury (Gabrielli et al., 2012; Lanari et al., 2012; Teissier et al., 2014). The pathogenesis of CMV infection in the CNS seems to be strongly related to perturbations in neural migration, neural death, cellular compositions, and the immune system of the brain (Cheeran et al., 2009). In infants with severe symptomatic congenital CMV infection, histopathologic evidence of viral dissemination is commonly found in the brain, ear structures, retina, liver, lung, kidney, and endocrine glands (Bissinger et al., 2002). Distinctive features include large cells with large nuclei containing oval inclusions (“owl’s eye” appearance). Inclusion-bearing epithelial cells have been described in the semicircular canals, vestibular membrane, cochlea, and other structures of the ear (Teissier et al., 2011; Gabrielli et al., 2013). Temporal bone anomalies with cochlear, vestibular, and auditory canal defects have been noted in association with hearing loss in affected infants (Davis, 1969; Myers and Stool, 1968; Bernard et al., 2015).

Clinical Presentation, Sequelae, and Prognosis

Prenatal ultrasonography provides clues to the possible diagnosis of fetal CMV infection. Findings include IUGR, microcephaly, ventriculomegaly, periventricular calcifications, echogenic bowel, polyhydramnios, pleural effusion, pericardial effusion, hepatosplenomegaly, intrahepatic calcifications, pseudo-meconium ileus, and placental enlargement (Nelson and Demmler, 1997; Guerra et al., 2008; Swanson and Schleiss, 2013). Fetal hydrops is also a common finding (Sampath et al., 2005). Abnormal prenatal findings on ultrasound examination were associated with increased risk of sequelae (Lipitz et al., 2013). However, the sensitivity of maternal ultrasonography to detect fetal CMV infection is unpredictable, given that most congenitally infected infants are asymptomatic. In a study of 600 pregnant women with primary CMV infection, abnormal ultrasound findings were detected in only 51 of 600 pregnancies (8.5%) and in only 23 of 154 fetuses (14.9%) in which congenital infection was documented. Thus the positive predictive value of an abnormal ultrasound finding that predicted symptomatic congenital infection in women with primary CMV infection was only 35.3% when fetal infection status was unknown, compared with 78.3% when congenital CMV infection was confirmed (Guerra et al., 2000, 2008). Another similar study noted that fetal ultrasound anomalies were detected in 37.7% of pregnant women with primary CMV infection acquired in early pregnancy in the setting of proven fetal infection (Leyder et al., 2016). When maternal ultrasonographic imaging was normal in the setting of proven fetal infection, CNS symptoms or signs were nonetheless noted in 53% of infants (Amir et al., 2016).

Signs and symptoms are apparent at birth in 10%–15% of all children with congenital CMV infection. Table 37.1 outlines the clinical manifestations of symptomatic CMV infection. Infection in the symptomatic infant can involve any organ and manifests itself along a spectrum from mild illness to severe disseminated multiorgan system disease. The mortality rate associated with symptomatic congenital CMV disease in the first year of life is estimated to be greater than 10% (Boppana et al., 1992). Clinical features include jaundice, hepatosplenomegaly, lethargy, respiratory distress, seizures, and petechial rash. Infants with symptomatic disease are often premature and small for their gestational age. A wide spectrum of disease can be observed, including hemolysis, bone marrow suppression, hepatitis, pneumonitis, enteritis, and nephritis. Long bone abnormalities have been described, reminiscent

• **Fig. 37.5** Magnetic resonance image abnormalities in infants with congenital cytomegalovirus (CMV) infection with neurologic manifestations. (A) T1 axial flair image of a neonate with congenital CMV infection with a diagnosis of central nervous system malformation in utero by prenatal ultrasonography, demonstrating severe hydrocephalus and cortical dysplasia and polymicrogyria. (B) Axial T1 image of an infant with symptomatic congenital CMV infection demonstrating ventriculomegaly and periventricular enhancement (arrow). (C, D) T1 fast low-angle shot axial (C) and sagittal (D) images of a symptomatic, congenitally infected infant demonstrating ventriculomegaly, polymicrogyria, and porencephalic cyst (arrow).

of those observed in congenital syphilis (Alessandri et al., 1995). Common laboratory abnormalities include thrombocytopenia, anemia, abnormal levels of liver enzymes (particularly elevated levels of transaminases), and elevated conjugated bilirubin levels.

Of particular concern are the CNS diseases observed with symptomatic congenital CMV infection, including meningoencephalitis, calcifications, microcephaly, neuronal migration disturbances, germinal matrix cysts, ventriculomegaly, and cerebellar hypoplasia (Cheeran et al., 2009; Gabrielli et al., 2012; Lanari et al., 2012). CNS disease is usually characterized by at least one of the following signs and symptoms: lethargy, microcephaly, intracranial calcifications, hypotonia, seizures, hearing deficit, or an abnormal eye examination finding, such as chorioretinitis or optic atrophy. The finding of microcephaly at birth typically indicates CNS involvement (Fig. 37.5). Long-term neurodevelopmental disabilities are observed in 50%–90% of children who are symptomatic at birth. In contrast, long-term neurodevelopment impairment appears to be less likely in congenitally infected infants who are asymptomatic at birth: when it does occur, injury is typically limited to sensorineural hearing loss (SNHL). Several studies have suggested that the intellectual development of asymptomatic congenitally infected infants appears to be normal (Conboy et al., 1986, 1987). Among symptomatic congenitally infected infants, long-term sequelae can include microcephaly, hearing loss, motor deficits (paresis or paralysis),

cerebral palsy, intellectual disability, seizures, ocular abnormalities (chorioretinitis, optic atrophy), and learning disabilities (Sharon and Schleiss, 2007; Cheeran et al., 2009).

The incidence of SNHL among children with congenital CMV infection ranges from 10% to 15% of those who are asymptomatic at birth to up to 60% of those who are symptomatic as newborns (Pass, 2005). SNHL can be progressive and fluctuating in both asymptomatic and symptomatically congenitally infected infants (Rosenthal et al., 2009). Among asymptomatic congenitally infected infants, SNHL tends to be high frequency in nature; it ranges in severity from a unilateral, mild hearing deficit to severe, bilateral, profound deafness. CMV-induced SNHL is a dynamic, evolving lesion; it may be present at birth or can appear later in childhood. Delayed-onset hearing loss usually occurs before 4 years of age (Williamson et al., 1992; Fowler et al., 1997; Dahle et al., 2000; Rivera et al., 2002; Madden et al., 2005) but has been reported to evolve and progress through 6 years of age and beyond. The pathogenesis of SNHL is related to an inflammatory labyrinthitis (Schleiss and Choo, 2006; Teissier et al., 2011; Gabrielli et al., 2013; Teissier et al., 2016). Some temporal bone and cochlear abnormalities have been described in a small case series of hearing-impaired infants with congenital CMV infection (Bauman et al., 1994), but CMV-associated SNHL is not associated with enlarged vestibular aqueduct syndrome (Pryor et al., 2005). Vestibular

disorders may occur independently of SNHL (Karlton et al., 2014; Bernard et al., 2015). The presence of petechiae and IUGR at birth are associated with the development of SNHL (Rivera et al., 2002). All congenitally infected infants, regardless of the results of functional hearing assessment at birth, should be monitored prospectively for SNHL. For severe SNHL, cochlear implantation has been used with success (Lee et al., 2005; Yoshida et al., 2009; Shin et al., 2011).

Diagnosis and Infant Assessment

Congenital CMV infection is best diagnosed by detection of virus, either through culture or via PCR, in samples collected in the first 2 to 3 weeks of life. The timing of collection of these samples is important because subsequent viral isolation beyond 3 weeks of age may represent neonatal infections acquired in the birth canal or after exposure to breast milk (Schleiss, 2006b) and not congenital infection. Urine and saliva are the clinical samples of choice for virus detection. Rapid confirmation of infection can be made with centrifugation culture ("shell vial") assays with a high sensitivity and specificity (Gleaves et al., 1984; Rabella and Drew, 1990; Revello and Gerna, 2002), although culture-based assays are largely being replaced in clinical virology laboratories by PCR. The magnitude of the systemic viral load measured by PCR in the congenitally infected infant may be a predictor of neurodevelopmental prognosis (Lanari et al., 2006).

Serodiagnosis of congenital CMV infection is problematic. In congenital CMV infection, antibody production by the infected fetus begins in utero; however, serodiagnosis of congenital infection is complicated by the presence of maternal IgG antibodies that cross the placenta. Although a negative antibody titer test result in infant and maternal sera provides sufficient evidence to exclude the diagnosis of congenital CMV infection, positive IgG titer test results in the newborn by no means confirm congenital infection. The presence of IgM antibodies to CMV in cord or neonatal blood is highly specific and in principle represents fetal antibody response, but IgM serologic tests have limited sensitivity in diagnosing congenital CMV infection (Revello et al., 1999b).

A recent development in molecular diagnostics for congenital CMV infection has been the use of dried blood spots (DBSs) as a source of CMV DNA for PCR-based detection (Barbi et al., 2006; Scanga et al., 2006; Yamagishi et al., 2006). DBS screening is amenable to long-term storage, so diagnosis can be made retrospectively, even after several years. There has been considerable interest in development of this test for implementation of widespread population-based newborn screening for congenital CMV infection (Walter et al., 2008; Dollard et al., 2010; Kharrazi et al., 2010). However, recent evidence from a large multicenter study suggests that DBS screening is not sufficiently sensitive for diagnosis of congenital CMV compared with detection in other bodily fluids such as saliva and urine (Boppana et al., 2010; Atkinson et al., 2013). An alternative approach would be to analyze the DBSs obtained from infants who failed newborn hearing screens, because congenital CMV infection can be identified in approximately 3% of such cases (Choi et al., 2009; Ross et al., 2017). This approach would allow early detection and more timely intervention; however, it would fail to identify those congenitally infected infants who pass the newborn hearing screening but later develop SNHL.

Cranial ultrasonography, head CT, and brain MRI are used to detect brain lesions associated with congenital CMV infection. CNS anomalies can be detected in some infants in utero. Fetal MRI can also detect abnormalities, including microcephaly and cortical anomalies, even when the ultrasonographic findings are

normal; this appears to be the preferred modality for diagnosis of fetal CNS involvement (see Fig. 37.5; Benoist et al., 2008; Doneda et al., 2010). Because the finding of CNS disease is a potential harbinger of permanent sequelae, diagnostic CNS imaging is warranted in all suspected cases of congenital infection (Boesch et al., 1989; Boppana et al., 1997; Kylat et al., 2006; Ancora et al., 2007; Gabrielli et al., 2012; Lanari et al., 2012; Capretti et al., 2014). Any of the standard imaging modalities is valuable in assessing CNS involvement. Ultrasonography, because of its convenience, is an appropriate initial study and is particularly valuable and sensitive in detecting periventricular calcifications and lenticulostriate vasculopathy associated with mild to moderate ventricular dilatation. MRI provides important additional information, particularly the presence of associated polymicrogyria, hippocampal dysplasia, and cerebellar hypoplasia (de Vries et al., 2004; Capretti et al., 2014); therefore the staged sequential use of an initial cranial ultrasound followed by MRI is probably the preferred approach to CNS imaging in this setting.

Careful initial hearing evaluation and longitudinal monitoring for SNHL are required in all infants with documented congenital CMV infection, given that this complication is the most common late sequela of congenital CMV infection. Early recognition of SNHL and institution of appropriate interventions (speech-language therapy, centers for deafness education, and cochlear implants) can markedly improve the developmental, social, and language skills of a child with hearing impairment. Any child born with congenital CMV infection, whether symptomatic or not, deserves careful and recurring evaluation for cognitive delays, visual impairment, or motor disabilities. Follow-up evaluation should consist of a multidisciplinary team approach including an infectious diseases specialist, pediatric otolaryngologist, and child behavioral-developmental specialist, in addition to a physical therapist, ophthalmologist, and neurologist as needed. Mothers of infants with congenital CMV infection should be counseled regarding future pregnancies. For infants with symptomatic congenital CMV infection born to women with low CMV IgG avidity antibodies (Society for Maternal-Fetal Medicine et al., 2016), some authorities recommend they be monitored for emergence of high-avidity antibody before future pregnancies are contemplated.

Treatment: Antiviral Intervention in the Newborn and the Pregnant Patient

Successful results with the use of antiviral therapies against CMV in immunosuppressed patients (Razonable, 2005; Boeckh and Ljungman, 2009; Vora and Englund, 2015) have helped drive the advent of antiviral treatment for congenital CMV infection (Hilgendorff et al., 2009; Lombardi et al., 2009; Amir et al., 2010; Yilmaz Çiftdoğan and Vardar, 2011). The benefits of ganciclovir in congenitally infected infants have been demonstrated in controlled trials. In a phase III, randomized, nonblinded controlled trial of ganciclovir for newborns with congenital CMV disease (Kimberlin et al., 2003), a group of infants with virologically confirmed congenital CMV infection received a 6-week course of IV ganciclovir therapy (6 mg/kg every 12 hours). The primary end point was improved hearing or retention of normal hearing. A statistically higher likelihood of normal or improved hearing at 6 months of age was noted in treated infants compared with controls. In a follow-up assessment, infants with symptomatic congenital CMV infection involving the CNS who received IV ganciclovir therapy had fewer developmental delays at 6 and 12 months, as assessed by the Denver Developmental Screening Test, compared with untreated infants (Oliver et al., 2009). On the basis of these

encouraging results, a randomized, placebo-controlled trial of oral valganciclovir therapy in neonates with symptomatic congenital CMV disease was recently conducted. In this study, all participants received valganciclovir (at a dosage of 16 mg per kilogram of bodyweight orally twice daily) for 6 weeks. Participants then underwent randomization in a 1:1 ratio to receive either continued valganciclovir therapy or placebo for 4.5 months. Hearing was more likely to be improved or to remain normal at 12 months in the 6-month treatment group than in the 6-week treatment group, and this group also had better neurodevelopmental scores on the Bayley Scales of Infant and Toddler Development (Nassetta et al., 2009; Kimberlin et al., 2015). Because antiviral therapy improved hearing and neurodevelopmental outcomes, 6 months of oral valganciclovir therapy should be considered for all infants with congenital CMV infection with any evidence of CNS involvement (microcephaly, abnormal CNS imaging, CSF positive for CMV DNA, chorioretinitis, or evidence of SNHL). Careful monitoring for neutropenia, the major side effect of valganciclovir therapy, is essential.

Ganciclovir therapy should also be used in any infant with severe or life-threatening end-organ CMV disease, whether acquired via congenital infection or by a postnatal route, such as via breastfeeding in a low birth weight premature infant (Table 37.2; Schleiss and McVoy, 2004). CMV retinitis in the congenitally infected infant can be a particularly problematic management issue; it has been reported that antiviral therapy for up to 6 months may be required to control chorioretinitis in the symptomatic congenitally infected infant (Shoji et al., 2010). All infants with documented congenital infection should have an ophthalmologic evaluation. If chorioretinitis is present, it should be managed in consultation with an ophthalmologist and infectious diseases expert.

Although ganciclovir improves neurodevelopmental outcomes for symptomatic infants, it is not yet clear whether ganciclovir holds the promise of improving outcomes in infants with asymptomatic congenital CMV infection. Because some of these infants are at risk of progressing to SNHL, clinical trials are warranted to explore whether antiviral therapy could prevent development of hearing loss.

The prospect of treating the pregnant patient to prevent transmission of CMV to the fetus is an area of active investigation. Ganciclovir has demonstrated teratogenic risk in some studies (Schleiss and McVoy, 2004); although this has never been demonstrated in humans, there is limited research in this area. A case report of the use of orally administered ganciclovir in a pregnant liver transplant patient did not show any evidence of teratogenicity (Pescovitz, 1999). Ganciclovir has been demonstrated to cross the placenta, and therefore could theoretically be used to treat CMV infection in utero (Brady et al., 2002). An observational study of 20 women with 21 fetuses, with confirmed congenital CMV infection treated with orally administered valacyclovir, demonstrated placental transfer of valacyclovir with measurable concentrations in the amniotic fluid and a subsequent reduced viral load in the fetal blood (Jacquemard et al., 2007). There have been several case reports of treatment of congenital CMV infection in utero with oral, parenteral, or intraamniotic administration of ganciclovir with various degrees of success (Revello et al., 1993; Miguelez et al., 1998; Revello and Gerna, 1999; Puliyanda et al., 2005). Maternal therapy with high-dosage oral valacyclovir therapy (8 g/d) has also been studied in women known to be carrying a CMV-infected fetus (Leruez-Ville et al., 2016; Leruez-Ville and Ville, 2017).

Passive immunization with CMV human immunoglobulin (HIG) has been studied for the in utero treatment and prevention

of congenital CMV infection. CMV HIG is a pooled, high-titer immunoglobulin preparation derived from donors with high levels of CMV antibody. Nigro et al. (2005) completed an uncontrolled and unblinded prospective study of CMV HIG for the treatment of pregnant women with primary CMV infection, including some women with confirmed fetal CMV infection (Nigro et al., 2005). Improvement was reported in the CMV HIG-treated patients with respect to ultrasonographic abnormalities in fetal brain and in placenta (La Torre et al., 2006; Schleiss, 2006a; Nigro et al., 2008), and reduced infection rates were observed compared with untreated controls. However, a randomized, blinded placebo-controlled trial of CMV HIG for the treatment and prevention of congenital CMV infection failed to demonstrate a benefit (Revello et al., 2014). It thus remains unclear if CMV HIG is useful in prevention of viral transmission or sequelae. A National Institutes of Health-funded multicenter randomized, placebo-controlled trial of CMV HIG during pregnancy in the setting of primary maternal infection is currently ongoing, and it is hoped that this study will shed light on this question (<https://clinicaltrials.gov/ct2/show/NCT01376778?term=brenna+anderson&rank=3>).

Natal Acquisition of Cytomegalovirus Infection: Implications for the Premature Infant

In addition to congenital infection, CMV can produce disease in the newborn after natal acquisition; this can occur via one of three mechanisms: (1) transmission in the birth canal during vaginal delivery after exposure to infectious cervicovaginal secretions, (2) through ingestion of breast milk, and (3) via blood transfusion. Of these potential mechanisms, the most common is via breast milk (Schleiss, 2006b), with transmission in the birth canal occurring less commonly. It has long been recognized that CMV is shed by the cervix (Montgomery et al., 1972) and excreted in the breast milk of seropositive women (Hayes et al., 1972; Stagno et al., 1982). CD14⁺ cells appear to play a major role in transmission of CMV by lactation (Maschmann et al., 2015). The risk of CMV transmission in infants who are breastfed by seropositive women shedding virus in their breast milk has been reported to be between 58% and 69% (Stagno et al., 1980; Dworsky et al., 1983). CMV infection acquired in the postnatal period in healthy term infants by this route is typically asymptomatic, only rarely producing any morbidity. There is no convincing evidence that acquisition of CMV via breast milk leads to any adverse neurodevelopmental sequelae (Kurath et al., 2010). In a study of CMV transmission through breastfeeding, all the infants who acquired CMV infection had normal neurodevelopment at a mean follow-up of 51 months of age (Vollmer et al., 2004). There is evidence that acquisition of CMV infection in the premature infant may contribute to the development of chronic lung disease (Kelly et al., 2015; Mukhopadhyay et al., 2016). Moreover, a recent study that examined long-term neuropsychologic sequelae in adolescents born before term identified early postnatal CMV infection as a risk factor for scoring significantly lower than those without CMV with respect to their overall cognitive abilities (Brecht et al., 2015; Wright and Permar, 2015).

Breast milk-acquired CMV can cause high infection rates and significant symptomatic disease in premature infants. In one study of very low birth weight (VLBW) premature infants (<32 weeks' gestation, <1500 g) exposed to CMV via breast milk, virus transmission occurred in 33 of the 87 exposed infants (Maschmann et al., 2001). Approximately half of these infants were ill and exhibited symptoms such as hepatopathy, neutropenia, thrombocytopenia, and sepsis-like deterioration. Other reports of early postnatal CMV

infection acquired by preterm infants from breast milk in highly immune populations have suggested a lower rate of symptomatic CMV infection (Mussi-Pinhata et al., 2004; Kurath et al., 2010; Josephson et al., 2014). The Centers for Disease Control and Prevention (CDC) has estimated that up to 4.5% of VLBW and premature infants in the United States may develop CMV sepsis syndrome because of breast milk–acquired CMV infections, resulting in approximately 2000 infants annually (Lanzieri et al., 2013). Proposed efforts to reduce the infectivity of breast milk from seropositive mothers have included freezing breast milk at -20°C , Holder pasteurization, and short-term pasteurization (Hamprrecht et al., 2004). Of these methods, freezing is the most studied and most likely to maintain the salutary immunologic properties of breast milk. Some experts recommend freeze-thawing of all breast milk before the VLBW premature infant is fed if the mother is known to be CMV seropositive or if her CMV serostatus is unknown. Although freezing of breast milk may lower the incidence of postnatally acquired CMV infection, it does not entirely eliminate the risk (Maschmann et al., 2006; Omarsdottir et al., 2015). Other interventions, such as microwave irradiation, can eliminate CMV from human milk (Ben-Shoshan et al., 2016), but it is unknown what impact this intervention has on the nutritional and immunologic components of milk. It is presumed that VLBW premature infants are at increased risk because they possess fewer transplacentally acquired antibodies against CMV than do term babies and thus are more likely to develop disease on infection. Treatment of the VLBW infant with IVIG appeared to reduce the likelihood of transmission of CMV by breast milk (Capretti et al., 2009), although this is not currently considered to be an indication for the use of IVIG in the premature infant. Further evidence is necessary to make recommendations regarding what, if any, interventions are appropriate in low birth weight, preterm infants receiving breast milk from CMV-seropositive mothers.

Transfusion-associated CMV infections were at one time a major problem in the neonatal intensive care setting (Yeager et al., 1981; Adler et al., 1983, 1984; Adler, 1986). Two approaches are currently used to decrease the risks of transfusion-associated CMV infection: leukocyte reduction and directed transfusion of CMV-negative blood products (Lamberson et al., 1988). Although leukocyte reduction has had a dramatic effect on the risk of transfusion-associated CMV infection, reports are conflicting in the literature regarding the question of whether this intervention is completely effective at eliminating the risk of transfusion-transmitted CMV infection (Fergusson et al., 2002; Vamvakas, 2005; Allain et al., 2009). A survey of the American Association of Blood Banks physician membership revealed that 65% of those responding believed that leukocyte-reduced and CMV-negative blood components were equivalent in their ability to prevent transfusion-associated transmission of CMV (Smith et al., 2010). A prospective, multicenter birth-cohort study conducted at three neonatal intensive care units (NICUs) in the United States found no evidence of transfusion-associated CMV infection when leukocyte-reduced blood was used for transfusion of VLBW infants (Josephson et al., 2014). These data support the practice of transfusing leukocyte-reduced blood products to premature infants, including blood from CMV-seropositive donors, since this practice should be adequate for preventing virtually all cases of transfusion-associated CMV infection in the NICU.

Prevention

One important strategy for addressing the problem of congenital CMV infection is the education of women of childbearing age

about the risks of transmission and strategies for prevention. Child care providers (including day care workers, special education teachers, and therapists) appear to have a higher risk of occupational exposure to CMV because of extensive contact with infants and young children (Pass et al., 1986; Adler, 1989; Pass et al., 1990). Education on the potential occupational risk in this group is essential. In contrast to these child care providers, healthcare workers who appropriately use routine infection control practices are not at increased risk of CMV acquisition. CMV infections in pregnant women are typically clinically “silent.” Like most healthy individuals, more than 90% of pregnant women with primary CMV infections have no symptoms. When symptoms occur, they are nonspecific and vague, often described as a flulike syndrome. Potential manifestations include fever, fatigue, headache, myalgia, lymphadenitis, and pharyngitis, but these are the exception and not the rule. Because most maternal CMV infections are asymptomatic, a major goal is education of all women of childbearing age on hygienic practices (American College of Obstetrics and Gynecologists, 2002; Jeon et al., 2006; Ross et al., 2006). Hygienic strategies are important because the saliva and urine of infected children are significant sources of CMV infection among pregnant women. Strategies include washing hands whenever there is contact with a child’s saliva or urine, not sharing food, utensils, or cups, and not kissing a child on the mouth or cheek (Cannon and Davis, 2005; Anderson et al., 2008a). It is also essential that women become better educated on the importance of CMV infection. A survey of women in 2005 showed that only 14% of women knew what CMV was, but most believed that preventative measures for an infection that could harm an unborn baby would generally be acceptable (Ross et al., 2008). The effectiveness of educating pregnant women on methods to prevent CMV transmission has been demonstrated (Adler et al., 1996). In a study in which seronegative mothers with a child in group day care were instructed on measures to prevent CMV transmission, pregnant mothers had a significantly lower rate of CMV infection than nonpregnant mothers attempting conception (Adler et al., 2004). In addition, a study in France demonstrated a lower CMV seroconversion rate after pregnant women had been counseled on hygienic measures (Vauloup-Fellous et al., 2009).

Prenatal maternal screening for CMV antibodies is controversial. Because women who are CMV immune can be reinfected with new strains that can then be transmitted to the fetus, with subsequent sequelae (Boppa et al., 1999, 2001; Ross et al., 2010; Yamamoto et al., 2010), a positive preconception titer test result for CMV IgG antibody may provide a false sense of reassurance and decrease a pregnant patient’s motivation to engage in careful hygienic practices. A study that evaluated three screening strategies suggested that universal maternal screening for CMV could be a cost-effective strategy if a treatment were available that could achieve a 47% reduction in disease incidence (Cahill et al., 2009).

Ultimately the control of congenital CMV infection could be realized by the development of an effective vaccine. No CMV vaccines are currently licensed; however, because of the enormous economic impact of congenital CMV infection, the Institute of Medicine has identified a CMV vaccine as the highest-level priority for new vaccine development (excluding HIV vaccines) for the United States (Stratton et al., 2001). A vaccine based on the CMV major envelope glycoprotein gB has demonstrated modest efficacy against acquisition of primary CMV infection in young, CMV-seronegative women in clinical trials (Pass et al., 2009; Bernstein et al., 2016). A consensus workshop sponsored by the US FDA concluded that CMV vaccine studies should be targeted at evaluating protection against congenital CMV infection, an essential precursor

to the development of congenital CMV disease with attendant sequelae (Krause et al., 2013). Other clinical trials are ongoing, including evaluation of live, attenuated CMV vaccines; subunit vaccines targeting other key proteins involved in the humoral and cellular immune responses to CMV infection; and disabled, single-cycle, replication-deficient vaccines that express key CMV proteins but are incapable of establishing infection (Schleiss, 2008; Fu et al., 2014).

Human Herpesvirus 6 and 7

HHV-6 was isolated in tissue culture in 1986 from peripheral blood leukocytes of patients with both lymphoproliferative disorders and HIV infection (Bernstein and Schleiss, 1996; Schleiss, 2009). For several years after its discovery, its role in disease was unclear, but it is now known to be the major etiologic agent of roseola infantum (exanthem subitum) and has been implicated in other clinical syndromes. HHV-6 is a prototypical β -herpesvirus, with a double-stranded DNA genome contained within an icosahedral capsid, surrounded by an outer envelope. HHV-6 is subclassified as either variant A or variant B, on the basis of differences in nucleotide sequence, restriction enzyme profile, and reactivity with monoclonal antibodies. HHV-6B is the subtype typically associated with roseola infantum (Yamanishi et al., 1988). HHV-6 and HHV-7 are ubiquitous in nature and typically cause infection in the first 2 years of life. A recent study in Ugandan infants demonstrated that more than 75% of infants acquire HHV-6 infection in the first year of life (Gantt et al., 2016).

HHV-7 is highly related to HHV-6 and, like HHV-6, is responsible for roseola infantum (Tanaka et al., 1994). HHV-7 is a β -herpesvirus, structurally and molecularly similar to CMV and HHV-6. As with HHV-6, infection with HHV-7 appears to be ubiquitous, although infection appears to be acquired somewhat later in life than HHV-6 infection (Suga et al., 1997; Caserta et al., 1998). Approximately 40%–45% of children have antibodies to HHV-7 by 2 years of age, and 70% of children are seropositive by 6 years of age. Both HHV-6 and HHV-7 can be found by PCR in cervical secretions, suggesting a possible (but unconfirmed) route for intrapartum transmission (Okuno et al., 1995; Dahl et al., 1999; Caserta et al., 2007).

Vertical transmission of HHV-6 DNA is described. Examination of 305 umbilical cord blood samples in one study identified HHV-6 DNA by PCR in 1.6% of infants (Adams et al., 1998). Congenital HHV-6 transmission was first definitively reported in a study of 5638 umbilical cord bloods; 57 samples (1%) had HHV-6 DNA by PCR, but none had HHV-7 (Hall et al., 2004). Of note, these infections were all asymptomatic, and it is not clear if this vertically transmitted DNA reactivates to produce bona fide virus particles. Vertical transmission of HHV-6 most often occurs (90% of cases) not from actively replicating virus but because of the germline passage of HHV-6 integrated into the chromosome (Hall et al., 2008). This germline mode of inheritance of the HHV-6 genome in this form of vertical transmission appears to be exclusively maternal (Hall et al., 2010). The clinical consequences of such transmission and the differences in germline transmission of the viral genome and the more common postnatal acquisition of HHV-6 in early childhood remain unknown, although recent evidence suggests that there may be long-term neurodevelopmental concerns in infants who have germline transmission of viral DNA (Caserta et al., 2014). The HHV-6 genome appears to integrate into the telomere—a chromosomal component important in cellular aging and in cancer—suggesting that there may be long-term consequences

associated with vertical germline transmission (Nacheva et al., 2008; Arbuckle et al., 2010). HHV-6 DNA can also be found in breast milk. Perinatal transmission via this mechanism has been postulated (Joshi et al., 2000) but has not been demonstrated.

Kaposi Sarcoma–Associated Herpesvirus and Epstein–Barr Virus

In 1994 a novel herpesvirus, KSHV (HHV-8), was identified in patients with AIDS-associated Kaposi sarcoma (KS) (Chang et al., 1994). This virus was assigned to the γ -herpesvirus subfamily of the *Herpesviridae*, on the basis of its molecular and sequence similarity to the other prototypical γ -herpesvirus, EBV. Subsequent studies have linked KSHV to both AIDS-associated KS and the endemic forms of KS that are prevalent in elderly Mediterranean men. A cross-sectional study of the seroprevalence of KSHV in children and adolescents in the United States indicated a prevalence of approximately 1% (Anderson et al., 2008b). There appears to be considerable regional variation in prevalence in the United States. In a population of children in south Texas, the seroprevalence was 26%, strongly suggesting that nonsexual modes of transmission predominate (Baillargeon et al., 2002). In sub-Saharan Africa, prevalence in children is even higher, approaching 60% in some studies (Sarmati, 2004). Endemic forms of pediatric KS are relatively common in sub-Saharan Africa and are associated, in some cases, with single-gene inborn errors of immunity (Jackson et al., 2016). There are reports of infections in infants that suggest possible vertical transmission, but congenital infection has not been demonstrable by PCR techniques (Sarmati et al., 2004). KSHV can also be transmitted by blood transfusion (Hladik et al., 2006); this observation suggests that transplacental transmission is at least theoretically feasible. In a study of 89 KSHV-seropositive women, KSHV DNA was detected in the peripheral blood mononuclear cells of 13 mothers (14.6%); KSHV DNA was detectable in the peripheral blood mononuclear cells of 2 of 89 samples drawn at birth from neonates born to these mothers. KSHV has also been demonstrated to infect placental cells, suggesting that a transplacental route of infection is feasible (Di Stefano et al., 2008). These findings suggest that KSHV can be transmitted perinatally but infrequently (Mantina et al., 2001). As serologic and nucleic acid–based diagnostic tests become more widely available, a better assessment of the worldwide seroepidemiology of KSHV infection and an increased understanding of its modes of transmission will be achievable. The clinical presentation of KSHV infection in immunocompetent children has been described (Andreoni et al., 2002). Fever and rash appear to be important findings with primary infection. Additional information on the epidemiology and modes of transmission of this pathogen, particularly in the prenatal and intrapartum period, is needed.

As for KSHV, there is a minimal amount of information available about prenatal and perinatal modes of transmission of EBV. EBV is the causative agent of infectious mononucleosis and is associated with nasopharyngeal carcinoma, Burkitt lymphoma, and lymphoproliferative disease in immunocompromised patients (Schleiss, 2009). Primary EBV infection during pregnancy appears to be rare (Le et al., 1983; Avgil and Ornoy, 2006). It is not clear whether transplacental passage of EBV in seropositive pregnant women occurs. It has been postulated that high-titer antibodies cross the placenta and protect the fetus from hematogenous transmission of virus in women who reactivate EBV during pregnancy (Purtilo and Sakamoto, 1982). A solitary case report describes the occurrence of severe EBV disease in a premature

infant, born at 28 weeks' gestation, who was examined on the 42nd day of life with hepatosplenomegaly, hemolytic anemia, thrombocytopenia, and atypical lymphocytosis (Andronikou et al., 1999). In another study, the potential for EBV vertical transmission from a seropositive mother to her child was evaluated in 67 pregnant women by nested PCR (Meyohas et al., 1996). Two of 67 neonates were positive for EBV DNA. In six pregnant women with evidence of primary EBV infection, four pathologic births were observed: one spontaneous abortion, two premature babies, one of whom died, and one stillborn with multiple malformations (Icart et al., 1981), although intrauterine EBV infection was not demonstrated. Placentas and some fetuses were studied in five cases of pregnancy interruption caused by maternal infectious mononucleosis in early gestation (Ornoy et al., 1982). Studies of pregnancy outcomes in the setting of primary maternal EBV infection have demonstrated necrotizing deciduitis, endovascularitis, perivascularitis, and occasional vascular obliteration in placental villi, as well as mononuclear and plasma cell infiltrates, although once again direct virologic evidence for EBV infection of these tissues was lacking (Ornoy et al., 1982). EBV DNA was identified in amniotic fluid and placenta in another case report (Tomai, 2011). A 2% congenital EBV transmission rate has been described in HIV-infected newborns (Gumbo et al., 2014). EBV DNA has also been detected in newborn blood spot screening cards from children with cerebral palsy (McMichael et al., 2012).

Human Parvovirus B19

Parvovirus B19, a small, single-stranded DNA virus, is the only member of the parvovirus family that causes human disease. The virus was identified in 1975 (Cossart et al., 1975) and was first linked to a disease in 1981—aplastic crisis in children with sickle cell anemia (Pattison et al., 1981). Primary infection with parvovirus B19 is commonly known as *fifth disease* or *erythema infectiosum*; it is classically described as a childhood exanthem with a “slapped cheek” appearance (Anderson et al., 1984). Considerable interest in the role of this virus in the pathogenesis of hydrops fetalis (nonimmune) and fetal aplastic crisis has evolved since the first cases of fetal death associated with maternal parvovirus B19 infection were reported in the 1980s (Brown et al., 1984; Kinney et al., 1988). The spectrum of parvovirus B19–associated diseases continues to expand and includes neurologic disease, arthritis, and autoimmune disease (Watanabe and Kawashima, 2015; Kerr, 2016; Mauermann et al., 2016; Palermo et al., 2016).

Epidemiology

Parvovirus B19 infection is common in childhood and continues at a low rate throughout adult life. One study identified an annual seroconversion of 1.5% in women of childbearing age unrelated to their occupation (Koch and Adler, 1989). The peak incidence of erythema infectiosum is in the late winter and early spring. Periodic epidemics at intervals of a few years are typical. The virus is spread by respiratory droplets (Anderson and Cohen, 1987), by blood products (especially pooled clotting factor concentrates; Jordan et al., 1998), and transplacentally (Ergaz and Ornoy, 2006). Approximately 50%–80% of adults in the United States are seropositive for human parvovirus B19 (Anderson, 1987; Vyse et al., 2007). A significant proportion of childbearing women are thus susceptible to infection (Markenson and Yancey, 1998; Yaegashi et al., 1998). Preconception seroprevalence to parvovirus B19 ranges from 24% to 84% (Ergaz and Ornoy, 2006). During pregnancy

the risk of acquiring parvovirus B19 infection is low, ranging from 0% to 16.5% in different studies (Ergaz and Ornoy, 2006). The risk of primary maternal infection is higher during epidemics of erythema infectiosum (Woernle et al., 1987; Kerr et al., 1994).

It is estimated that one-fourth to half of maternal parvovirus B19 infections result in transmission of infection to the fetus (Gratacos et al., 1995; Alger, 1997; Koch et al., 1998). The vast majority of pregnancies are unaffected (Berry et al., 1992; Sheikh et al., 1992). The risk of adverse fetal outcome is increased if maternal infection occurs during the first two trimesters of pregnancy (Skjoldbrand-Sparre et al., 2000), particularly before 20 weeks' gestation. There are conflicting reports regarding the prognosis once fetal infection has been established. A longitudinal study of fetal morbidity and mortality in more than 1000 women with primary parvovirus B19 infection in pregnancy demonstrated a risk of fetal hydrops of 3.9% and a risk of fetal death of 6.3%; fetal death was observed only if maternal infection occurred before the 20th week of gestation (Enders et al., 2004). A retrospective analysis of intrauterine parvovirus B19 infection at a single site suggested that the rate of adverse fetal outcome is much higher than previously appreciated, with fetal hydrops and demise occurring in more than 10% of pregnancies (Beigi et al., 2008), although the total number of cases reported in this series was low; this primarily represented a referral population to a tertiary care center. In an analysis of nearly 1000 cases of fetal and newborn demise caused by various infectious agents, parvovirus B19 was found to be responsible for 63% of all of the virus-related deaths occurring before live birth (Williams et al., 2013), even in the absence of a history of frank hydrops fetalis. Thus the spectrum of diseases associated with parvovirus B19 infection remains incompletely defined.

Pathogenesis

The most common mode of transmission of parvovirus B19 is via a respiratory route. Typically, once the virus establishes infection, viremia occurs, followed by mild systemic symptoms such as fever and malaise. Viremia is short lived, lasting only 1 to 3 days, and the characteristic immune-mediated rash develops 1 to 2 weeks later. Once the rash appears, an individual is no longer infectious. Arthropathy caused by parvovirus B19 is common; it is observed more frequently in adults with primary infection than in children. Symptoms usually subside within 1 to 3 weeks, although approximately 20% of affected women have persistent or recurring arthropathy for months to years (Woolf et al., 1989).

Potential pathogenic mechanisms involve the recognized affinity of parvovirus B19 for progenitor erythroid cells of bone marrow. The blood group P antigen is a main cellular receptor for parvovirus B19, and it is found on red blood cells and on placental trophoblast cells (Jordan et al., 2001). The P antigen is also expressed on fetal cardiac myocytes, enabling parvovirus B19 to infect myocardial cells (Rouger et al., 1987), leading to myocarditis (von Kaisenberg et al., 2001). Myocarditis induced by parvovirus B19 can contribute to high-output cardiac failure, and the myocardial inflammation and subendocardial fibroelastosis may also contribute to fetal hydrops (Morey et al., 1992). Fetal infection most likely occurs hematogenously via the placenta during maternal viremia. Parvovirus B19 infection in utero causes a pronormoblast arrest, which leads to fetal anemia, nonimmune hydrops, and sometimes progressive congestive heart failure (Kinney et al., 1988; Ergaz and Ornoy, 2006). The fetus is especially susceptible to adverse consequences

of red blood cell infection, secondary to the intrinsic short fetal erythrocyte life span and rapidly expanding blood volume, especially during the second trimester. It has also been postulated that parvovirus B19 infection leads to cytotoxicity and subsequent anemia by inducing apoptosis of infected red blood cells (Yaegashi et al., 1999, 2000). The nonstructural 1 (NS1) protein of parvovirus B19 induces cell death by apoptosis in erythroid-lineage cells by a pathway that involves caspase 3, whose activation may be a key event during parvovirus B19-induced cell death (Moffatt et al., 1998). The NS1 protein also has a key role in the arrest of infected cells at the G₁ phase of the cell cycle before apoptosis induction (Chisaka et al., 2003).

In addition to erythroid precursors and myocytes, other organs appear to be involved in fetal parvovirus B19 infection. Fetal brain infection has been reported. Neuropathologic findings in the infected hydropic fetus include perivascular calcifications, primarily in the cerebral white matter, as well as multinucleated giant cells. Viral DNA has been demonstrated in the brain and liver (Isumi et al., 1999). Data also suggest that the maternal cell-mediated immune response at the placental level contributes to the pathogenesis of congenital infection. In one study, placentas from women whose pregnancies were complicated by parvovirus B19 infection had increased infiltration of CD3 T cells and elevated levels of interleukin-2 (Jordan et al., 2001).

Clinical Spectrum

Parvovirus B19 infection causes erythema infectiosum, or fifth disease, in normal hosts, aplastic crisis in patients with hemolytic disorders, and chronic anemia in immunocompromised hosts. A substantial proportion of infected adult women may also have arthropathy in association with parvovirus B19 infection (Woolf et al., 1989). Maternal symptoms have been present in up to two-thirds of documented cases of nonimmune hydrops fetalis associated with parvovirus B19 infection (Yaegashi et al., 1998).

The major clinical presentation of parvovirus B19 infection in the fetus is hydrops fetalis. Various estimates suggest that human parvovirus B19 infection contributes from 10%–27% of cases of nonimmune hydrops fetalis (Yaegashi et al., 1994; Essary et al., 1998; Markenson and Yancey, 1998). Nonimmune hydrops fetalis was the main complication in 0.9%–23% of pregnancies among proven maternal infections with parvovirus B19 (Ergaz and Ornoy, 2006). A risk of 7.1% for hydrops fetalis has been described for pregnant women who acquire parvovirus B19 infection between 13 and 20 weeks' gestation (Enders et al., 2004). The role that parvovirus B19 plays in intrauterine fetal demise in the absence of hydrops fetalis is incompletely defined (Riipinen et al., 2008; Williams et al., 2013). In addition to hydrops fetalis, in recent years there have been increasing numbers of case reports of neurologic and ophthalmologic anomalies associated with fetal parvovirus B19 infections. Although some studies undertaken to examine the association between fetal infection and congenital anomalies failed to reveal any associations (Mortimer et al., 1985; Kinney et al., 1988), in other studies parvovirus B19 has been a cause of neuronal migration defects (Pistorius et al., 2008). The role of parvovirus B19 in neurodevelopmental injury has not been fully explored. There have been at least three case reports of fetal encephalopathy associated with in utero infection with parvovirus B19 (Alger, 1997).

Parvovirus B19 has been implicated in some cases of congenital anemia (Heegaard and Brown, 2002). In one series of 11 children with a diagnosis of Diamond–Blackfan syndrome, 3 of 11 bone

marrow aspirates revealed evidence of parvovirus B19 DNA. All three of these children, but none of the parvovirus B19 PCR-negative cases, underwent spontaneous remission (Heegaard et al., 1996). In light of these data, all infants undergoing evaluation for congenital anemias should be evaluated for the possibility of parvovirus B19 infection. Long-term persistence of parvovirus B19 DNAemia (>1 year) with concomitant red blood cell aplasia has been described in the context of congenital infection (Lejeune et al., 2014; Hudson et al., 2015; Nadimpalli et al., 2015). Congenital parvovirus B19 infection has also been associated with bone lesions in long and axial bones (Cantey et al., 2013).

Laboratory Evaluation

In primary care the diagnosis of human parvovirus B19 infection is most commonly made clinically through recognition of the characteristic rash. Serologic confirmation is necessary in high-risk situations, such as after a significant exposure of a pregnant woman to a child with erythema infectiosum. Both radioimmunoassays and enzyme-linked immunosorbent assays are available for detection of human parvovirus B19-specific IgG and IgM antibodies (Kinney and Kumar, 1988). The presence of anti-parvovirus B19 IgM in fetal blood or amniotic fluid may confirm fetal infection but is not a sensitive test as it may be detected in only one-fifth of infected fetuses (Torok et al., 1992). False-positive results of parvovirus B19 IgM testing have been reported, including cross-reactions with anti-rubella IgM (Dieck et al., 1999).

Monitoring of the pregnant patient with evidence of a primary parvovirus B19 infection is important. The woman should be counseled regarding risks of fetal transmission, fetal loss, and hydrops, and serial ultrasound examinations should be performed every 1 to 2 weeks, up to 12 weeks after acute infection, to detect development of anemia and hydrops (Crane et al., 2014). The findings of echogenic bowel, ascites, pleural or pericardial effusion, or scalp edema are considered to be important markers of fetal infection and disease. Middle cerebral artery Doppler imaging for evaluation of fetal anemia may be another useful prospective surveillance tool, because fetal anemia can be detected with this technique before fetal hydrops is evident (Feldman et al., 2010). In the context of a human parvovirus B19 infection in a symptomatic, pregnant woman, elevated or rising weekly measurements of maternal alpha fetoprotein suggest fetal infection, and rising concentrations may be a marker for an increased risk of hydrops fetalis (Carrington et al., 1987). However, some studies have failed to demonstrate any association between the magnitude of the elevation of the alpha fetoprotein level and the severity of fetal anemia (Simms et al., 2009). A number of commercial PCR assays are available, and these can be performed on serum, amniotic fluid, or fetal tissue. Presumptive diagnosis can also be made on the basis of finding IgM antibody in the maternal and fetal blood. PCR for parvovirus B19 DNA or in situ hybridization studies can be performed with maternal blood, amniotic fluid, cord blood, or fetal tissues. The detection of parvovirus B19 DNA in maternal blood has excellent diagnostic sensitivity, and new-generation enzyme immunoassays and IgG avidity assays appear to hold promise for improved serodiagnosis during pregnancy (Enders et al., 2006, 2008).

Treatment

Spontaneous resolution of fetal hydrops with normal neonatal outcome has been reported in approximately one-third of cases

(Humphrey et al., 1991; Sheikh et al., 1992; Rodis et al., 1998a). Because two-thirds of fetuses do not recover without intervention, fetal transfusion is usually recommended (Boley and Popek, 1993; Brown et al., 1994). The earlier fetal transfusion is attempted, the more likely it is to be successful. Cordocentesis allows precise assessment of the magnitude of fetal anemia, which can then be corrected by blood transfusion, typically using packed red blood cells. With this approach, outcomes have been favorable in most reported series, even among severely anemic fetuses. In one report, packed red blood cell transfusion was performed in 30 patients with fetal anemia (hemoglobin values ranging from 2.1 to 9.6 g/dL). The overall survival rate was 83.8% (Schild et al., 1999). In a report of 13 patients with severe hydrops fetalis who received intrauterine transfusion, 11 survived (84.6%), whereas all the nontransfused fetuses with severe hydrops fetalis died (Enders et al., 2004). A retrospective review of 20 fetuses with parvovirus B19 infection complicated by severe anemia and/or fetal hydrops reported a survival rate of 76% for fetuses undergoing one or more transfusions (Macé et al., 2014).

Prognosis

Mortality rates for fetal hydrops resulting from all nonimmune causes continue to exceed 50%, even with current aggressive therapies and intensive care (Wy et al., 1999; Huang et al., 2007; Macé et al., 2014). Hydrops secondary to parvovirus B19 infection seems to have a better outcome than that from other causes (Ismail et al., 2001; Enders et al., 2004). Although few long-term prospective studies of infants born to mothers with documented primary parvovirus B19 infection have been conducted, most report normal developmental outcome. Parvovirus B19 has recently been recognized as a cause of CNS injury in older children, including encephalitis, meningitis, stroke, and peripheral neuropathy (Douvoyiannis et al., 2009), but two prospective studies in the United Kingdom of approximately 300 congenitally exposed infants found the risk of major congenital or developmental abnormality to be less than 1% (Miller et al., 1998), and there is minimal risk of long-term morbidity or death in childhood following primary maternal infections in pregnancy (Lassen et al., 2013). A case-control study involving approximately 200 mother-infant pairs found no differences in frequency of developmental delay between infants born to women with confirmed primary parvovirus B19 infection during pregnancy and infants born to women with evidence of preconceptional immunity (Rodis et al., 1998b). Other studies have also suggested a favorable long prognosis in children born to women with primary parvovirus B19 infections during pregnancy (Miller et al., 1998).

Prevention

If a pregnant woman has a significant exposure to an infectious case of parvovirus B19, counseling should be provided regarding the potential risk of infection. Anti-parvovirus IgM and IgG serologic analyses and serum PCR should be performed; if they show evidence of primary infection, then serial fetal ultrasonographic evaluations should be performed. Postexposure passive immunization with immunoglobulin is not currently recommended because the period of maternal viremia has passed by the time the diagnosis of acute parvovirus B19 infection is made (Boley and Popek, 1993). Although high-dose IVIG has been used to attempt to prevent hydrops fetalis during pregnancy in the setting of acute infection (Selbing et al., 1995), treatment with this modality in the pregnant

woman or the neonate has not been shown to improve fetal outcomes. Human IgG monoclonal antibodies with potent neutralizing activity have been generated, and these are suggested as candidates for the development of immunotherapeutic approaches for individuals chronically infected with parvovirus B19 or for acutely infected pregnant women (Gigler et al., 1999), but these interventions are not commercially available. There has been limited progress in the development of a candidate parvovirus B19 vaccine. Phase I studies of a recombinant vaccine based on baculovirus-produced capsids have been conducted, and this vaccine was found to have a favorable safety and immunogenicity profile (Bansal et al., 1993). Efforts are under way to research and develop vaccines to prevent parvovirus B19 infections with use of other expression systems (Lowin et al., 2005).

Pregnant healthcare providers should be counseled about the potential risks to their fetus from parvovirus B19 infections and should, at a minimum, wear masks and use standard droplet precautions when caring for immunocompromised patients with chronic parvovirus B19 infection or patients with parvovirus B19-induced aplastic crises. Some hospitals exclude pregnant healthcare providers from caring for these high-risk patients, but this issue remains controversial.

Rubella

Rubella virus is an enveloped, single-stranded, positive-sense RNA virus belonging to the family *Togaviridae*. Humans are the only known natural host for rubella virus. Rubella, commonly known as *German measles*, usually results in a mild illness with an accompanying exanthem in adults and children; however, rubella produces serious consequences in pregnant patients, in whom fetal infection can lead to serious anomalies. An ophthalmologist, Norman Gregg, offered the first description of CRS in 1941 while investigating an epidemic of neonatal cataracts (Gregg, 1941). Not until the global pandemic of 1964 to 1965, however, were the multiple teratogenic manifestations of CRS fully appreciated and the permanent neurodevelopmental consequences for newborns fully recognized. The capacity to grow the virus in tissue culture led rapidly to the development of a vaccine and subsequently an immediate reduction in the incidence of CRS in the United States and other developed countries, followed by efforts to eradicate indigenous CRS in the Western hemisphere (Papania et al., 2014). However, CRS is still encountered in the developing world, and unfounded concerns about the safety of measles-mumps-rubella vaccine have set the stage for potential reemergence of these diseases, because of decreased vaccine adherence in the context of routine well-child care (Omer et al., 2009; Grabenstein, 2013; Bahta and Ashkir, 2015). Therefore a working knowledge of the identification of the clinical manifestations of CRS remains highly relevant to the neonatologist.

Epidemiology

Since the development of rubella vaccine in 1969, the incidence of rubella in the United States has decreased dramatically. The annual incidence of rubella cases has dropped 99%, from 58 per 100,000 population in 1969 to less than 0.5 per 100,000 population in 1997 to 1999 (Danovaro-Holliday et al., 2001). CRS cases in the United States have demonstrated a similar dramatic decline, and in 2004 the CDC concluded, against the background of few or no reports of rubella activity from the 50 states and the virtual absence of reported CRS, that endemic rubella had been eliminated

from the United States (Centers for Disease Control and Prevention, 2005; Plotkin, 2006; Reef et al., 2006), although occasional importation cases had been described through the early 2000s (Castillo-Solórzano et al., 2003; Andrade et al., 2006). However, by mid-2015, endemic rubella had been declared to be eliminated from the Americas (Lambert et al., 2015; Kirby, 2015; Shrivastava et al., 2015). CRS may nonetheless be encountered in the United States in infants of mothers emigrating from countries with no or suboptimal national vaccination programs (Fang et al., 2013). Rubella is still an important and potentially preventable cause of birth defects globally, with more than 100,000 cases of CRS occurring annually in developing countries (Vynnycky et al., 2016).

Maternal rubella that occurs between the month before conception and the second trimester of pregnancy may be associated with transmission of infection and, depending on the timing of infection, disease in the infant. The frequency of congenital infection after maternal rubella with a rash is 70%–85% if infection occurs during the first 12 weeks of gestation, 30%–54% during the first 13 to 16 weeks of gestation, and 10%–25% at the end of the second trimester (Miller et al., 1982; South and Sever, 1985). The classic findings of congenital rubella are most typically associated with the onset of maternal infection during the first 8 weeks of gestation (Miller et al., 1982). Both the risk of fetal infection and the severity of disease decline after the first trimester, and the risk of any teratogenic effect is extremely low after 17 weeks' gestation (Lee and Bowden, 2000).

Pathogenesis

Rubella virus is transmitted via respiratory droplets. Once the oral or nasopharyngeal mucosae have been infected, viral replication occurs in the upper respiratory tract and nasopharyngeal lymphoid tissue. The virus then spreads contiguously to regional lymph nodes and hematogenously to distant sites. Fetal infection is believed to occur as a consequence of maternal viremia. The mechanism by which rubella infection of the fetus leads to teratogenesis has not been fully determined, but the cytopathology in infected fetal tissues suggests necrosis, apoptosis, or both, as well as inhibition of cell division of precursor cells involved in organogenesis (Lee and Bowden, 2000; Atreya et al., 2004). The rubella replicase protein p90 interacts with a cellular cytokinesis-regulatory component (i.e., the citron kinase) in the process leading to tetraploidy and cell cycle arrest. In tissue culture a number of unusual manifestations of rubella virus replication have been observed, including mitochondrial abnormalities and disruption of the cytoskeleton. Characteristic markers of apoptosis such as DNA fragmentation, nuclear chromatin condensation, and annexin V staining can be observed following rubella virus infection in cell culture. Microarray analysis following rubella virus infection in cell culture demonstrated upregulation of cytokines and interferon (IFN), suggesting that the induction of inflammatory responses may serve as another possible mechanism of injury induced by rubella (Adamo et al., 2008). Cells infected with rubella virus form a unique cytoplasmic fiber network resembling microtubules, which appears to facilitate cell-to-cell spread of the rubella virus genome even in the absence of infectious virus particles (Matthews et al., 2010). Astrocytes have been shown to be permissive for rubella virus replication in cell culture (Chantler et al., 1995). Macrovascular fetal endothelial cells have also been found to be highly permissive for rubella virus replication, suggesting that the vascular diseases in CRS are triggered by persistent rubella virus infection of endothelial cells (Perelygina et al., 2013, 2015). The importance of endothelial cells as targets

of infection in the developing fetus was also demonstrated by histopathologic examination of three cases of fatal CRS that demonstrated rubella virus antigen in interstitial fibroblasts in the heart, adventitial fibroblasts of large blood vessels, alveolar macrophages, progenitor cells of the outer granular layer of the brain, and capillary endothelium and basal plate in the placenta (Lazar et al., 2016). Fetuses infected with rubella virus demonstrate cellular damage in multiple sites, and a noninflammatory necrosis is observed in multiple target organs, including eyes, heart, brain, and ears (Lee and Bowden, 2000).

Clinical Spectrum

The peak incidence of endemic rubella is in the late winter and early spring months. Up to 50% of primary infections are asymptomatic. The period of maximal communicability extends from a few days before until 7 days after onset of the rash. Often a prodrome of mild systemic symptoms precedes the rash by 1 to 5 days. Viremia can be detected as early as 9 days before the onset of rash. Lymphadenopathy, which can precede a rash, is often present in the posterior auricular or suboccipital region. The rash classically begins on the face and spreads caudally to the trunk and extremities. Symptoms generally last up to 3 days, and the incubation period ranges from 14 to 21 days. Transmission by breastfeeding in a case of postpartum acquisition of infection has been described (Klein et al., 1980). The typical illness in adults and children with acquired rubella consists of an acute generalized maculopapular rash, fever, and arthralgias, arthritis, or lymphadenopathy. Conjunctivitis is also common. Encephalitis (1 in 5000 cases) and thrombocytopenia (1 in 3000 cases) are complications (Chaari et al., 2014).

Infants with congenital rubella are usually born at term but are often small for their gestational age. The most common isolated sequela is hearing loss (Ueda et al., 1979; Miller et al., 1982). The next most common findings are heart defects, cataracts, low birth weight, hepatosplenomegaly, and microcephaly. The triad of deafness, cataracts, and congenital heart disease constitutes the classic syndrome (Bouthry et al., 2014). In addition, systemic illness can occur and can be characterized by purpura, hepatosplenomegaly, jaundice, pneumonia, and meningoencephalitis; 45%–70% of infants have cardiac lesions, including patent ductus arteriosus, peripheral pulmonic stenosis, and valve abnormalities (Schluter et al., 1998; Reef et al., 2000). An extensive review of published reports of cardiovascular disease in the setting of CRS demonstrated that branch pulmonary artery stenosis is the most commonly identified isolated lesion (Oster et al., 2010). Death caused by pulmonary hypertension has been described in the setting of untreated patent ductus arteriosus caused by CRS (Toizumi et al., 2014). Additional ocular findings are pigmentary retinopathy, microphthalmia, and strabismus. Skin lesions have been described as resembling a blueberry muffin and represent extramedullary dermal hematopoiesis; an identical rash can be observed in congenital CMV infection (Brough et al., 1967; Bowden et al., 1989; Avram et al., 2007; Mehta et al., 2008).

The clinical manifestations of CRS differ to some extent depending on the timing of fetal infection. In a prospective study following up pregnant women with confirmed rubella by trimester, a full range of rubella-associated defects (including congenital heart disease and deafness) were observed in nine infants infected before the 11th week. Thirty-five percent of infants (9 of 26) infected between 13 and 16 weeks' gestation had deafness alone (Miller et al., 1982). Cataracts typically occur secondary to maternal rubella occurring before day 60 of pregnancy; heart disease is found almost exclusively

when maternal infection is before the 80th day (i.e., first trimester). Disease manifestations that may have their onset after birth (late-onset disease) include a generalized rash with seborrheic features that may persist for weeks, acute or chronic interstitial pneumonia, abnormal hearing resulting from presumed labyrinthitis, central auditory imperception, and progressive rubella panencephalitis (Phelan and Campbell, 1969; Sever et al., 1985; Reef et al., 2000; Franklin and Kelley, 2001). Infants with congenital rubella appear to shed virus in the oropharynx for the first several months of life (Nagasawa et al., 2016).

A higher than expected incidence of autoimmune diseases, such as thyroid disorders and diabetes mellitus, has also been reported years after the diagnosis of congenital rubella (McEvoy et al., 1988; Reef et al., 2000; Forrest et al., 2002; Gale, 2008). Abnormalities in dental development, including evidence of hypoplastic enamel of the developing teeth, have been described in children with CRS (Bhatia et al., 2012). Infants with late-onset disease have demonstrated immunologic abnormalities, including dysgammaglobulinemia or hypogammaglobulinemia (Soothill et al., 1966; Hayes et al., 1967; Hancock et al., 1968). Hyper-IgM syndrome has also been described in association with autoimmune disease in a child with CRS (Palacin et al., 2007). Other studies have demonstrated dysfunction of cellular immune responses in children with CRS (Fuccillo et al., 1974; South et al., 1975; Verder et al., 1986). Psychiatric disturbances, including some with features of autism spectrum disorders, have been observed decades after CRS (Hwang and Chen, 2010).

Laboratory Evaluation

It is common obstetric practice to screen all pregnant women for rubella virus antibodies, and because of the devastating consequences of CRS, this is a reasonable policy to continue, even in the setting of eradication of endemic rubella in the United States. Women who are exposed to rubella should be screened for evidence of previous immunity; if none is found, they should be tested for rubella virus IgG and IgM antibodies. A positive IgM titer or a rise in paired IgG titers is indicative of recent infection. Women with such findings should also be evaluated to try to determine the likely gestational age at the time of infection to assess the potential risk to the fetus.

The laboratory diagnosis of congenital rubella can be made definitively only during the first year of life, unless the virus can be recovered later from an affected site, such as the lens. Diagnosis can be confirmed by a positive rubella IgM titer; a significant acute-to-convalescence change in IgG titer; isolation of rubella virus from nasal, blood, throat, urine, or CSF samples; or detection of viral nucleic acid by reverse transcriptase (RT) PCR from the throat, CSF, or lens (obtained during cataract surgery). An infected infant can excrete the virus for many months after birth despite the presence of neutralizing antibody and thus may pose a hazard to susceptible individuals (Nagasawa et al., 2016).

Other laboratory findings include thrombocytopenia, hyperbilirubinemia, and leukopenia. There is relatively little information about maternal ultrasonographic findings in CRS (Yazigi et al., 2017), largely because the syndrome had become rare by the time routine ultrasonographic screening during pregnancy became standard. Radiographic findings include a large anterior fontanel, linear areas of radiolucency in the long bones (i.e., celery stalking), increased densities in the metaphyses, and irregular provisional zones of calcification (Reed, 1969; Chapman, 1991). The radiographic changes seen in rubella are not pathognomonic of the

disease but resemble those seen in other congenital viral infections, including congenital CMV infection (Alessandri et al., 1995).

Treatment and Prognosis

There is no specific antiviral therapy for congenital rubella. Initially the infant may need general supportive care, such as administration of blood transfusion for anemia or active bleeding, seizure control, and phototherapy for hyperbilirubinemia. Long-term care requires a multidisciplinary approach consisting of occupational and physical therapy, close neurologic and audiologic monitoring, and surgical interventions as needed for cardiac malformations and cataracts (Shah et al., 2014).

The consequences of fetal rubella may not be evident at birth. In one study of 123 infants with documented congenital rubella, 85% of cases were not diagnosed until after discharge from the nursery (Hardy, 1973). Communication disorders, hearing defects, some mental or motor retardation, and microcephaly by 1 to 3 years of age were among the major problems that were discovered after the newborn period. A predisposition for inguinal hernias was also noted. Longitudinal studies of somatic growth show that most infants with congenital rubella remain smaller than average throughout infancy but grow at a normal rate. Stunting of growth was more common after rubella virus infection in the first 8 weeks of pregnancy than after later infection. Even in the absence of intellectual disability, neuromuscular development is commonly abnormal. A study of neurodevelopmental outcomes in 29 affected children without intellectual disability found that 25 had other abnormalities: hearing loss, difficulties with balance and gait, learning deficits, and behavioral disturbances (Desmond et al., 1978).

Prevention

The critical intervention in prevention of CRS is to ensure that women who are considering pregnancy have been appropriately vaccinated. The Advisory Committee on Immunization Practices recommends screening of all pregnant women for rubella immunity and postpartum vaccination of those who are susceptible (McLean et al., 2013). Immunity to rubella appears to confer almost complete protection against CRS. Rare cases of documented subclinical maternal reinfection with rubella virus have been reported (Saule et al., 1988; Morgan-Capner et al., 1991). In rare cases, maternal reinfection can lead to CRS (Banerji et al., 2005). Approximately 20 cases of CRS after maternal reinfection have been reported in the literature, and none have caused symptomatic CRS when the known reinfection occurred after 12 weeks' gestation (Bullens et al., 2000).

Live attenuated rubella virus vaccine is safe and effective, although the duration of immunity is uncertain. It is currently administered in the United States in a trivalent formulation in combination with measles–mumps–rubella vaccine. The vaccine is recommended for children at 12 to 15 months of age and at 4 to 5 years of age. It is also recommended for women of childbearing age in whom the results of both a hemagglutination inhibition antibody test and a pregnancy test are negative. Although no cases of symptomatic congenital rubella have been reported as a consequence of vaccination during pregnancy in the more than 500 cases monitored, vaccination is not recommended during pregnancy because of the theoretical hazard to the fetus (Josefson, 2001; Tookey, 2001; Nasiri et al., 2009). A mild rubella-like illness is sometimes seen after immunization, with arthralgia occurring 10 days to 3 weeks after

injection. If a woman is found to be nonimmune, vaccine should be administered during the immediate postpartum period before discharge. Breastfeeding is not a contraindication to postpartum immunization. Immunization in the postpartum period has rarely produced polyarticular arthritis, neurologic symptoms, or chronic rubella viremia (Tingle et al., 1985).

The problem of treatment of the pregnant woman who is exposed to rubella or who contracts the disease should be resolved after the known risks have been weighed. If serum antibody is detectable at the time of exposure, the fetus is probably protected. If no antibody is detectable, additional serum samples should be obtained at 2 to 3 weeks after exposure and again at 4 to 6 weeks after exposure. These samples can be run concurrently with the first serum sample to ascertain whether infection has occurred (i.e., seroconversion). There is some evidence that administration of IVIG to a pregnant woman may prevent rubella virus infection or viremia (Young et al., 2015). IVIG can reduce the likelihood of fetal infection but will not eliminate the risk; therefore the CDC does not routinely recommend the use of IVIG in a pregnant woman for postexposure prophylaxis unless she does not wish to terminate the pregnancy. Decisions about the termination of pregnancy should be made only after maternal infection has been proved and should also account for the risk of rubella-associated damage to the fetus, which is highest when maternal infection occurs during the first 8 weeks of pregnancy.

Lymphocytic Choriomeningitis Virus

LCMV is a member of the family *Arenaviridae*. Rodents are the primary reservoir, particularly mice and hamsters. Like other arenaviruses, LCMV has a bisegmented negative-strand RNA genome. The S segment encodes the virus nucleoprotein and glycoprotein, whereas the L segment encodes the virus polymerase (L) and Z protein. Sequelae of human exposure to LCMV range from asymptomatic infection to nonspecific, flulike symptoms; a proportion of infections have neurologic manifestations. LCMV was first described as a cause of congenital infection in England in 1955 in a 12-day-old infant (Komrower et al., 1955) and later in the United States (Barton et al., 1993; Larsen et al., 1993; Barton et al., 2001; Barton and Mets, 2001). Because LCMV has only recently been recognized as a source of congenital infection, it is likely underdiagnosed (Jamieson et al., 2006).

Epidemiology

Human seroprevalence ranges between less than 1% and 10% worldwide and differs extensively with geographic region (Childs et al., 1991; Stephensen et al., 1992; Ambrosio et al., 1994; Marrie and Saron, 1998). One study noted a higher prevalence in women (Marrie and Saron, 1998). Studies conducted in the 1940s through the 1970s found that approximately 8%–11% of cases of aseptic meningitis and encephalitis were associated with LCMV infection (Meyer et al., 1960; Park et al., 1997a). In temperate climates, human exposure is more common during the fall and winter, when rodents move indoors. Outbreaks have been reported in laboratory personnel working with hamsters and mice (Hinman et al., 1975; Vanzee et al., 1975; Dykewicz et al., 1992). Multiple outbreaks associated with pet hamsters have also been reported in the United States (Biggar et al., 1975; Maetz et al., 1976) and Europe (Deibel et al., 1975; Brouqui et al., 1995); however, congenital infection is relatively rare. As of the early 2000s, 54 cases had been published worldwide since the initial reported case in 1955, and 27 of these

cases had occurred in the United States (Barton and Mets, 2001; Greenhow and Weinrub, 2003). There has been increased recognition of congenital LCMV in recent years; 34 of the cases described in a review were reported since 1993 (Jamieson et al., 2006). The true frequency of congenital LCMV infection is unknown, because there is no active surveillance. As with other congenital infections, there may be a wide spectrum of disease, including asymptomatic and subclinical or nonspecific infections.

Pathogenesis

Humans acquire LCMV infection from aerosolized particles, bites, or fomite contact with virus excreted from rodents (Jahrling and Peters, 1992). Human-to-human horizontal transmission by organ transplant has been documented (Fischer et al., 2006). The pathogenesis of LCMV infection is poorly understood, although it is likely an immunopathologic process mediated by the host CD8⁺ T-cell response (Craighead, 2000). It is also postulated that the high rate of spontaneous mutations that arise during LCMV replication allows both variability in pathogenicity and a mechanism of escape from humoral response during the initial phase of infection (Ciurea et al., 2001).

Like other arenaviruses, LCMV replicates either at the site of infection or in corresponding lymph nodes; this localized replication is followed by viremia. During the viremic stage the virus travels to parenchymal organs and the CNS. Pathologic findings include lymphocytic infiltration and extramedullary hematopoiesis. Chemokine and cytokine responses appear to be responsible for neurologic disease (Christensen et al., 2009), although LCMV inactivates the host innate type 1 IFN response, presumably as an immune evasion strategy (Borrow et al., 2010). These immune evasion mechanisms allow viral persistence in the infected host.

Clinical Spectrum

It is estimated that asymptomatic or mild LCMV infections occur in approximately one-third of patients infected; however, the classic presentation of LCMV infection is a nonspecific, flulike, or mononucleosis-like illness that is often biphasic. The symptoms include fever, malaise, nausea, vomiting, myalgias, headache, photophobia, pharyngitis, cough, and adenopathy. After defervescence and resolution of these constitutional symptoms, a second phase of CNS disease may develop. Neurologic manifestations occur in approximately one-fourth of infectious episodes and range from aseptic meningitis to meningoencephalitis. Transverse myelitis, Guillain-Barré syndrome, and deafness have also been reported. Other manifestations include pneumonitis, arthritis, myocarditis, parotitis, and dermatitis. Recovery may take months but usually occurs without sequelae (Craighead, 2000).

When LCMV infection occurs during pregnancy, maternal symptoms typically appear during the first and second trimesters, but only 50%–60% of mothers of infants with a diagnosis of congenital LCMV infection recall having symptoms (Wright et al., 1997). Known maternal exposure to rodents is reported in approximately one-fourth to one-half of cases (Barton and Mets, 2001). Usually, exposed women are from rural settings, come from lower socioeconomic settings with substandard housing conditions, or have pet rodents in the home (i.e., hamsters).

The complete spectrum of disease secondary to congenital LCMV infection is still uncertain, although the virus clearly targets the fetal brain and retina, potentially causing ventriculomegaly, hydrocephalus, chorioretinitis, and neurodevelopmental abnormalities

(Bonthius, 2012; Anderson et al., 2014). Chorioretinitis and hydrocephalus are the predominant characteristics reported among children with a diagnosis of congenital LCMV infection. Chorioretinitis is present in more than 90% of cases. Other ocular findings include chorioretinal scars, optic atrophy (usually bilateral), nystagmus, esotropia, exotropia, leukocoria, cataracts, and microphthalmia (Enders et al., 1999; Brezin et al., 2000; Barton and Mets, 2001). Some ophthalmologic findings resemble those described in the lacunar retinopathy of Aicardi syndrome (Wright et al., 1997). A wide range of neurologic defects are described, including microencephaly, encephalomalacia, chorioretinitis, porencephalic cysts, neuronal migration disturbances, periventricular infection, and cerebellar hypoplasia (Bonthius et al., 2007, 2012). Congenital LCMV infection should be considered in the differential diagnosis of neonatal hydrocephalus (Schulte et al., 2006).

Most infants are born at term, and birthweights are generally appropriate or large for gestational age. Thirty-five percent to 40% of infants reported with congenital LCMV infection have had microcephaly or macrocephaly at birth (Barton and Mets, 2001). Systemic symptoms are rare, although hepatosplenomegaly and jaundice have been noted. Other individual case report findings include pes valgus, dermatologic findings resembling staphylococcal scalded-skin syndrome (Wright et al., 1997), spontaneous abortion (Biggar et al., 1975), and intrauterine demise secondary to hydrops fetalis (Enders et al., 1999; Meritet et al., 2009; El Feghaly and Hunstad, 2013). It is important to note that because systemic symptoms are typically minimal at birth, the diagnosis of congenital LCMV infection may not be considered until an affected infant is a few months old, when microcephaly, macrocephaly, visual loss, or developmental delay may be noted.

Laboratory Evaluation

Serology is the most reliable and feasible method to diagnose LCMV infection. In most reports the diagnosis was established by testing of the infant's serum, CSF, or both; in some, maternal serum testing was the key. Testing of all three fluids provides the most information. Because of the low baseline population seroprevalence, positive LCMV titer test results are much more useful for diagnosis than detection of antibodies to microbes such as CMV and *Toxoplasma gondii*. There is a commercially available immunofluorescent antibody test that detects both IgM and IgG for LCMV. It has better sensitivity than the complement fixation and neutralizing antibody tests (Lewis et al., 1975; Lehmann-Grube et al., 1979). Complement fixation titers generally do not rise until more than 10 days after onset of infection, but immunofluorescent antibody results may be positive within the first few days of illness (Deibel et al., 1975). The CDC also has an enzyme-linked immunosorbent assay test for IgM and IgG; it may be more useful for diagnosis in an older child because it can detect increased IgG levels later than and persistent IgG for longer than the immunofluorescent antibody test. Some studies have found antibody as late as 30 years after suspected exposure. RT-PCR has been used in serum and CSF to diagnosis LCMV infection and as a surveillance tool; it may become more available in the future (Park et al., 1997b; Enders et al., 1999; McCausland and Crotty, 2008).

Information about routine laboratory data in patients with a diagnosis of congenital LCMV infection is minimal, but thrombocytopenia and hyperbilirubinemia have been reported. CSF findings are variable. Up to half of cases demonstrate a mild increase in white blood cell count (up to 64 cells per microliter in one case

series of 18 infants), the serum protein concentration may be normal or mildly elevated, and the serum glucose concentration may be normal or mildly decreased (Wright et al., 1997). Among infants reported in whom neuroradiographic imaging was performed, 89% (17 of 19) had hydrocephalus or periventricular calcifications. Flattened gyri, lissencephaly, and schizencephaly have been reported (Barton and Mets, 2001), compatible with a role for LCMV in fetal neuronal migration defects (Bonthius et al., 2007).

Treatment

Ribavirin has been used for management of other arenavirus infections and inhibits LCMV growth in vitro (Géssner and Lother, 1989). Although novel approaches are being used to develop antivirals against LCMV and other pathogenic arenaviruses (de la Torre, 2008), there are currently no recommendations for the use of antiviral agents against these viruses. In the outbreak associated with solid organ transplant, one affected recipient received ribavirin and reduced levels of immunosuppressive therapy and survived (Fischer et al., 2006).

Prognosis

Because congenital LCMV infections have been recognized relatively recently and the existing data come from case reports, there may be a wider spectrum of disease than is currently appreciated. The proportion of asymptomatic infected infants is unknown. In a review of 26 serologically confirmed infant cases, 9 infants (35%) died, and 10 (63%) of the 16 reported survivors had severe neurologic sequelae (Wright et al., 1997). Neurologic sequelae reported in the setting of congenital LCMV infection include microcephaly, spastic quadriplegia, mental retardation, developmental delay, seizures, and visual loss (Barton and Mets, 2001; Bonthius, 2012). SNHL is also described (Wright et al., 1997; Barton and Mets, 2001; Anderson et al., 2014; Cohen et al., 2014). Retinal disease is an underrecognized complication of congenital LCMV infection. A study in Chicago of patients prospectively diagnosed with chorioretinitis and patients in a home for severely mentally retarded children with chorioretinal scars found six children with elevated LCMV titers and negative evaluation for toxoplasmosis, CMV, rubella, and HSV (Mets et al., 2000). Similarly, two children with chorioretinal scars and elevated LCMV titers, suggesting congenital infection, have been reported in France (Brezin et al., 2000).

Prevention

Public health officials and clinicians should be aware that (1) wild, laboratory, and pet rodent exposure can lead to intrauterine infection with LCMV and (2) congenital infection has been associated with potentially devastating ophthalmologic and neurologic sequelae. Pregnant women need to be educated about the risks of exposure to infected rodent excreta and instructed to avoid rodents and rodent droppings. Obstetricians and neonatologists should seek a history of pet or wild rodent exposure for counseling purposes and to aid in the evaluation of infants with unexplained CNS diseases. The diagnosis of LCMV infection should be considered in all cases of infant hydrocephalus. There are currently no vaccines approved by the FDA for the prevention of arenavirus disease, although candidate multivalent arenavirus vaccines capable of providing T cell–mediated protection against a variety of pathogenic arenaviruses are currently in development (Botten et al., 2010).

Attenuated LCMV is also itself being used as a vector for vaccine development for heterologous pathogens (Ring and Flatz, 2016).

Enteroviruses

Enteroviruses are single-stranded, positive-sense RNA viruses. These viruses belong to the family *Picornaviridae* (*pico* means *very small* in Spanish). The enteroviruses of humans include polioviruses 1, 2, and 3, coxsackieviruses A and B (named after Cocksackie, New York, the city where these viruses were first identified and characterized), and the echoviruses (*echo* is an acronym for *enteric cytopathic human orphan*). Of these, poliovirus infection has historically been responsible for the greatest morbidity in infants. Severe, often fatal poliovirus disease used to occur with great frequency in infants infected in the perinatal period, with a high incidence of residual paralysis in survivors. Fortunately, poliovirus infections have become rare in the developed world, because of the widespread implementation of effective immunizations. However, neonatal diseases associated with coxsackieviruses and echoviruses, for which there are no vaccines, remain common and can be associated with serious morbidity and occasional death. Typically acquired from a maternal source, these agents are associated with a wide range of clinical syndromes in the NICU, including CNS infection, myocarditis, and a sepsis-like syndrome. Enteroviruses are also responsible for a large number of hospital readmissions for evaluation of febrile syndromes in infants younger than 2 months.

Epidemiology

Enterovirus infections are seasonal, occurring most commonly during summer and autumn in temperate climates. The incidence varies from year to year, with outbreaks sometimes caused by a single coxsackievirus or echovirus serotype and sometimes by several serotypes (Sawyer et al., 1994). In older children, enteroviruses are transmitted by the fecal–oral route and are typically associated with a variety of febrile syndromes, including febrile exanthematous syndromes, aseptic meningitis, pneumonia with or without pleural effusion, and myocarditis. Disease in newborns is relatively uncommon but reflects the frequency of infection in the general population (Kraiden and Middleton, 1983). Enteroviruses may also be associated with nosocomial outbreaks. Nursery and obstetric clinic outbreaks of both coxsackievirus B (Brightman et al., 1966; Rantakallio et al., 1970; Bhambhani et al., 2007) and echovirus (Nagington et al., 1978; Jankovic et al., 1999; Chen et al., 2005) infections have been reported and associated with severe, and sometimes fatal, illnesses.

Enterovirus infections account for at least one-third of neonatal febrile admissions for suspected sepsis and for between half and two-thirds of all admissions during the peak enterovirus season (Dagan, 1996; Byington et al., 1999). Neonatal aseptic meningitis is also frequently caused by enterovirus infections. In a review of neonatal meningitis seen over a 15-year period in Galveston, Texas, enterovirus was the most common cause of meningitis in newborns older than 7 days (Shattuck and Chonmaitree, 1992). Enteroviruses, along with other viruses, have been implicated as a potential cause of sudden infant death syndrome (SIDS), possibly from myocarditis or pulmonary infection (Shimizu et al., 1995; Grangeot-Keros et al., 1996), but this association has been controversial. In one study of SIDS victims, a comprehensive assessment was undertaken to attempt to identify potential viral infection of the myocardium. Overall, 62 SIDS victims and 11 controls were studied. Enteroviruses

were detected in 14 cases (22.5%), adenoviruses in 2 cases (3.2%), EBVs in 3 cases (4.8%), and parvovirus B19 in 7 cases (11.2%), whereas control group samples were completely negative for viral nucleic acid (Dettmeyer et al., 2004). However, another evaluation of histopathologic features and PCR analysis from 24 SIDS cases failed to demonstrate any association with viral infection (Krous et al., 2009), leaving this putative association unclear.

Etiology and Pathogenesis

Neonates can acquire enterovirus infections secondary to in utero transmission, intrapartum transmission during labor and delivery, or postnatally. Intrauterine infections appear to occur via transplacental spread, secondary to maternal viremia, and this mode of transmission appears to be responsible for up to 22% of cases of neonatal enterovirus infection (Kaplan et al., 1983; Modlin, 1986). Enteroviruses have been implicated as a cause of fetal demise (Nielsen et al., 1988; Johansson et al., 1992; Konstantinidou et al., 2007). Intrapartum or postnatal transmission is more common than transplacental transmission. The dominant mode of transmission of serious neonatal infection is through contact with maternal blood, fecal material, or vaginal or cervical secretions, most likely during or shortly after delivery (Jenista et al., 1984; Hawkes and Vaudry, 2005). After acquisition of infection, viremia ensues in the infant, leading to a variety of end-organ diseases. The presence or absence of transplacental maternally derived antibody also dictates the severity of the disease in the infected infant. Breastfeeding appears to provide a relative degree of protection against acquisition of infection in neonates (Sadeharju et al., 2007).

One of the most comprehensive analyses of the incidence of neonatal enterovirus disease came from a prospective study in Rochester, New York. This study demonstrated that approximately 13% of all newborns tested positive for enterovirus from throat or stool cultures during a typical season (June to October; Jenista et al., 1984). Although this result represented a remarkably high incidence, 79% of these infections were asymptomatic. The most common clinical findings in the 21% of symptomatic infections were lethargy and fever. These infants were typically admitted to a hospital for an evaluation to rule out sepsis, making enterovirus infection a more common reason for hospitalization because of an infectious disease than group B streptococcus, HSV, and CMV infections combined.

It appears that any of the nonpolio enteroviruses can cause disease in the newborn. A variety of clinical syndromes are associated with certain enteroviruses. A retrospective medical record review of 24 neonatal enterovirus infections in Toronto, Canada, found that 10 infants died, 12 had aseptic meningitis, and 5 had myocarditis (Kraiden and Middleton, 1983). Of the 24 isolates, 7 were echovirus, 15 were coxsackievirus B, 1 was coxsackievirus A, and 1 was nontypable. In infants with acute enterovirus disease requiring hospitalization, coxsackievirus B is associated primarily with myocarditis and aseptic meningitis (Kibrick and Benirschke, 1958). Recent reports have identified coxsackievirus B1 as an emerging cause of life-threatening myocarditis and other severe, fatal syndromes in neonates (Verma et al., 2009; Wikswo et al., 2009). Echoviruses are associated with severe nonspecific febrile illnesses with DIC (Nagington et al., 1978), aseptic meningitis (Cramblett et al., 1973), or hepatitis (Modlin, 1980). With both coxsackievirus and echovirus, nonspecific febrile illnesses, with or without an exanthem, are commonly observed. Enterovirus 71 is particularly notable for its etiologic role in epidemics of severe neurologic diseases in children (Chen et al., 2010). Nursery-based outbreaks

of infection with this neurovirulent enterovirus have also been described (Huang et al., 2010).

Except for transplacental infections, the portal of entry for enterovirus is via the oral or respiratory route. After replication in the pharynx and the GI tract, virus seeds the tonsils, cervical and mesenteric nodes, and Peyer patches. The pathogenesis of enterovirus disease stems from the ensuing viremia, which can lead to infection of the heart, CNS, liver, pancreas, adrenal glands, skin, mucous membranes, and respiratory tract. In coxsackievirus B infections, myocardial necrosis and inflammation may be seen that are patchy or diffuse, with extensive infiltration by lymphocytes, mononuclear cells, histiocytes, and polymorphonuclear leukocytes. Similar infiltrates are seen in the meninges in both coxsackievirus and echovirus aseptic meningitis. Brainstem encephalitis can be observed with enterovirus 71 infection, often in association with pulmonary edema (Wang and Liu, 2009). Fatal fulminant infections are often associated with echovirus 11 (Mostoufzadeh et al., 1983). Recently a severe enteroviral pneumonitis in children has been described caused by enterovirus 68, which was associated with wheezing, hypoxia, and pediatric intensive care unit admissions (Du et al., 2015; Esposito et al., 2015; McAllister et al., 2015; Principi and Esposito, 2015). Development of antibody is associated with recovery, although virus may continue to be shed in the stool for several weeks. Failure to clear enterovirus infection, particularly from the CNS, should suggest an underlying humoral immunodeficiency, although this would not typically be recognized in the neonatal period because of the presence of transplacentally acquired IgG (McKinney et al., 1987; Misbah et al., 1992).

Clinical Spectrum

When neonatal disease is acquired vertically from the mother, the infant is typically asymptomatic at birth, although premature delivery is more common. The mother may be febrile at this time or may have a history of recent high temperatures and GI symptoms. Fever, anorexia, and vomiting develop in the baby after an incubation period of 1 to 5 days. The onset of illness occurs in the first week of life in more than 50% of affected infants (Krajden and Middleton, 1983). At that point the clinical evolution depends on the infecting virus and the extent of end-organ involvement. In most instances the disease is mild and self-limited. Symptomatic infections may be characterized by rash, aseptic meningitis, hepatitis, and pneumonia. A review of 29 infants younger than 2 weeks with enterovirus infections reported that 5 of the infants had severe multisystem disease, and all survived (Abzug et al., 1993). In another study in Salt Lake City, 1779 febrile infants younger than 90 days and undergoing evaluation for sepsis were enrolled; 1061 were tested for enterovirus, and 214 (20%) were enterovirus positive (57% from blood and 74% from CSF). The mean age of infants with enterovirus infection was 33 days; 91% were admitted, and 2% required intensive care (Rittichier et al., 2005).

These observations underscore the generally benign and self-limited nature of neonatal enterovirus disease; however, morbidity can be substantial in severe disseminated disease. A viral sepsis syndrome—characterized by DIC, refractory hypotension, and death—may occur in the setting of severe disease. Typically these severe infections are acquired in the immediate perinatal period. The mother is commonly symptomatic and may have been empirically treated with broad-spectrum antibiotics for possible chorioamnionitis. A maternal history of suspected chorioamnionitis in the absence of positive bacterial cultures should suggest this

association, particularly during the typical “enterovirus season” observed in temperate climates. If myocarditis is present, congestive heart failure is often severe. Some infections, particularly those with echoviruses, are characterized by a rampant and overwhelming hepatitis (Modlin, 1980). Others exhibit primarily pulmonary disease or GI involvement, including diarrhea and necrotizing enterocolitis (Lake et al., 1976). Intracranial bleeding ranging from small to massive, severe hemorrhage has also been reported as a complication of neonatal enterovirus infection (Swiatek, 1997; Abzug and Johnson, 2000; Abzug, 2001). Other rarely associated findings include disseminated vesicular rash, dermal hematopoiesis, and hemophagocytic syndrome (Bowden et al., 1989; Barre et al., 1998; Sauerbrei et al., 2000). The severity of CNS infection is similarly variable. Moderate or mild meningitis is characterized by temporary irritability, lethargy, fever, and feeding difficulty.

Acquired postnatal enterovirus disease in infants is characterized primarily by high temperature, irritability, lethargy, or poor feeding. One-fourth of infected infants develop diarrhea or vomiting with or without an erythematous maculopapular rash. Conjunctivitis has also been observed. Respiratory tract symptoms are less common (Dagan, 1996). As noted, there is significant overlap between enteroviral and bacterial neonatal infections, and the two syndromes are difficult to distinguish; therefore many febrile infants will be admitted to the hospital and treated with broad-spectrum antibiotics and, if the CNS is involved, with acyclovir for possible bacterial sepsis and neonatal HSV infection. Such treatment seems unavoidable, except in circumstances in which enterovirus infection can be diagnosed rapidly and definitively. The duration of illness ranges from less than 24 hours to longer than 7 days but generally is 3 to 4 days.

Laboratory Evaluation

Viral culture from stool or rectal swab, nasopharyngeal swab, blood, buffy coat, urine, or CSF is the gold standard diagnosis. Stool or rectal swab cultures can remain positive for several weeks following the initial infection, underscoring the importance of fecal–oral transmission in the epidemiology of these infections. Recently, RT-PCR assays have become standardized and are available from many commercial and reference laboratories. Serologic tests for enteroviruses have been reported but are less useful than culture and PCR (Swanink et al., 1993).

Laboratory evaluation is predicated on the clinical syndrome and the end organs involved. Infants with aseptic meningitis typically have moderate CSF pleocytosis, which can be either lymphocytic or polymorphonuclear but may lack pleocytosis even in the setting of documented CNS infection (Seiden et al., 2010). Accordingly, during periods of active enterovirus infection in the community, CSF should be sent for PCR even if pleocytosis is absent. Thrombocytopenia, elevated transaminase levels, hyperbilirubinemia, hyperammonemia, hematologic abnormalities consistent with DIC, anemia, peripheral leukocytosis, and abnormal chest radiographs are among other potential laboratory findings. When myocarditis is a diagnostic possibility, echocardiogram and electrocardiogram are indicated and may reveal diminished left ventricular function or dysrhythmias. Liver biopsy and histopathologic examination may be warranted in cases of fulminant hepatic failure (Abzug, 2001; Muehlenbachs et al., 2015). For neonatal enterovirus disease, the dried umbilical cord has been used for retrospective, PCR-based diagnosis of in utero–acquired infection (Morioka et al., 2014).

Treatment

The cornerstone of treatment of neonatal enterovirus disease is supportive care. Myocarditis and heart failure can be treated with inotropic support, diuretics, aggressive fluid management, and other supportive measures. DIC should be treated with blood products and other supportive measures as indicated. There is no evidence that steroids are of benefit. IVIG has been reported anecdotally to treat neonatal enterovirus infections with various degrees of success (Valduss et al., 1993; Kimura et al., 1999). Only one randomized trial has systematically studied its use, in 16 neonates with severe enterovirus infection; nine of these infants were randomized to receive IVIG, at a dose of 750 mg/kg. Decreased viremia and viruria along with faster resolution of irritability, jaundice, and diarrhea were demonstrated in patients given IVIG with high titers of neutralizing enteroviral-specific antibodies. However, there were no significant differences in other major clinical outcomes, such as the duration of hospitalization, fever, and symptoms of acute illness between treatment and control groups (Abzug et al., 1995). To attempt to augment the enterovirus type-specific antibody level in the setting of symptomatic neonatal disease, maternal plasma transfusion has been attempted (Jantausch et al., 1995; Rentz et al., 2006), based on the rationale that neonates typically acquire infection from their mothers in the peripartum period. Although reports of success with use of IVIG for treatment of neonatal enterovirus infections are largely based on anecdotal reports in limited numbers of patients, its use should be considered for severely symptomatic infections with life-threatening end-organ disease.

The antiviral drug pleconaril has been developed specifically to treat picornavirus infections (enteroviruses and rhinoviruses). A small case series of infants with severe enteroviral hepatitis suggested a beneficial effect (Aradottir et al., 2001). Another small case series indicated that five of six neonates with severe enterovirus infection who were treated with pleconaril survived, with minimal or no sequelae (Rotbart and Webster, 2001). A multicenter study of pleconaril treatment of enteroviral meningitis in children younger than 12 months conducted by the CASG and sponsored by the National Institutes of Health demonstrated no significant differences in the duration of positivity by culture or PCR, hospitalization, or symptoms for the treatment and placebo groups (Abzug et al., 2003). Pleconaril did appear to have an effect on enteroviral meningitis in adults (Desmond et al., 2006), but the role of this drug in infants and children remains undefined. In a recent study of pleconaril for treatment of neonatal enteroviral sepsis, symptomatic infants with hepatitis, coagulopathy, and/or myocarditis and onset of disease at 15 days of life or earlier were randomized to receive either orally administered pleconaril or placebo for a 7-day treatment course. Shorter times to both culture and PCR negativity and a greater overall survival rate were observed among the pleconaril recipients (Abzug et al., 2016). Although other small-molecular inhibitors of picornavirus replication are in preclinical development (Smeets et al., 2016), additional trials of pleconaril for treatment of serious enterovirus disease in infants and young children are warranted.

Short-Term and Long-Term Prognosis

Prognostic factors for severe neonatal disease include peripartum maternal illness, earlier age of onset of neonatal disease, absence of serotype-specific antibody, and absence of fever and irritability (Abzug et al., 1993). All these risk factors are most consistent with

vertical intrauterine enterovirus infection rather than postnatally acquired infection. The highest mortality rates are associated with the combination of severe hepatitis, coagulopathy, and myocarditis. Severe hepatitis caused by enterovirus infection is associated with mortality rates ranging from 30% to 80% (Modlin, 1986; Abzug, 2001). By the time DIC has developed, the prognosis is grave. Prothrombin time longer than 30 seconds was a risk factor for death in one retrospective case review (Abzug, 2001).

Few long-term follow-up studies have been published, but the available information suggests that infants who survive severe enteroviral neonatal disease have a complete recovery in most instances. Outcomes of 6 of 11 survivors with follow-up ranging from 9 to 48 months included normal growth and no residual medical problems or liver dysfunction (Abzug, 2001). The long-term prognosis following CNS infection is unclear. A number of early studies of infants younger than 3 months with aseptic meningitis suggested that there may be some impairment of intellectual development in comparison with carefully selected control groups (Farmer et al., 1975; Sells et al., 1975). However, in a series of nine children with enteroviral meningitis and nine matched controls evaluated for sequelae at approximately 4 years of age, no differences in mean intelligence quotient, head circumference, detectable SNHL, or intellectual functioning were detected (Wilfert et al., 1981). A similar case-control follow-up study of 33 participants, compared with siblings used as controls, reported no neurodevelopmental sequelae (Bergman et al., 1987). Older children with enterovirus 71 CNS infection, however, are at risk of significant neurodevelopmental sequelae (Chang et al., 2007).

Prevention

Anecdotal reports of the use of IVIG in nursery outbreaks to prevent further horizontal transmission of enterovirus infection have produced conflicting results (Nagington et al., 1983; Caroleane et al., 1985; Kinney et al., 1986). Because there are multiple nonpolio enteroviral serotypes that cause clinical disease, design of antienteroviral immunization is conceptually difficult, although vaccines are in development for enterovirus 71 (Zhang et al., 2010; de Crom et al., 2016). Standard contact precautions should be used for the treatment of hospitalized infants with known or suspected enterovirus infections.

Human Parechovirus

Recently two viruses formerly classified with the echoviruses, echoviruses 22 and 23, were shown to comprise a separate genus within the family *Picornaviridae*, the genus *Parechovirus*. Bank voles and humans serve as natural hosts. There are currently four species in this genus: *Parechovirus A* (also known as *human parechovirus*), *Parechovirus B* (more commonly known as *Ljungan virus*), *Parechovirus C* (also known as *Sebokele virus*), and *Parechovirus D* (*Ferret parechovirus*). Seventeen distinct human parechovirus genotypes have now been recognized (Drexler et al., 2009; Pajkrt et al., 2009; Harvala et al., 2010; Renaud and Harrison, 2015). Genotype 1 is most commonly associated with GI illness, while genotype 3 is associated with neonatal sepsis and CNS infection (de Crom et al., 2016). These viruses have been recognized recently as significant neonatal pathogens (Harvala et al., 2010; Sharp et al., 2013). The primary sites of parechovirus replication are believed to be the respiratory tract and the GI tract. Replication in the GI tract is associated with prolonged shedding of infectious virus in the feces. As a result, fecal-oral transmission, as with enteroviruses,

appears to be the predominant route of infection. Parechovirus infections may also be acquired via a respiratory route, with subsequent virus shedding detectable in respiratory secretions. Viremia leads to secondary seeding of other organs and systemic symptoms.

Neonates with parechovirus infection, particularly parechovirus 3 infection, have a clinical presentation similar to infants with severe enterovirus disease, with a sepsis-like illness in severe cases (Verboon-Macielek et al., 2008a; Wolthers et al., 2008). Hepatitis is also a prominent feature of neonatal infection. The most frequent signs are fever, seizures, irritability, rash, and feeding problems. It has been postulated that parechovirus 3 infection is a newly emerging infection, and the relative lack of maternal antibody may predispose the neonate to more severe disease (Harvala et al., 2010). Parechovirus can also cause aseptic meningitis and encephalitis in the neonate, with the predominant site of injury being the periventricular white matter (Verboon-Macielek et al., 2008b; Levorson et al., 2009; Gupta et al., 2010). The findings noted by MRI can mimic those observed with hypoxic-ischemic encephalopathy (Amarnath et al., 2016). Parechovirus can cause aseptic meningitis in the absence of CSF pleocytosis (Sharp et al., 2013), usually associated with the type 3 parechovirus genotype (Harvala et al., 2011). Parechovirus RNA has also been found at autopsy in children younger than 2 years (Sedmak et al., 2010), including in infants with otherwise unexplained deaths. Having an older sibling in the household is an independent risk factor for acquisition of neonatal disease (Nielsen et al., 2016). In a case series of 13 patients with suspected CNS infection who were evaluated for parechovirus infection, nine infants had confirmed parechovirus encephalitis, and five demonstrated neurodevelopmental sequelae, including two with cerebral palsy and one with central visual impairment (Britton et al., 2016). In a retrospective analysis of more than 300 CSF samples collected over a 10-year period, the prevalence of parechovirus was higher than that of HSV, CMV, and VZV (Vollbach et al., 2015).

Ljungan virus, first described in 1998, has been the subject of recent interest because of its apparent role in the pathogenesis of type 1 diabetes in rodents and because of a possible emerging role in human disease (Tolf et al., 2009). The virus does not appear to have a role in the development of diabetes in humans (Tapia et al., 2010), although seroprevalence studies demonstrate that this infection does circulate by person-to-person transmission (Jääskeläinen et al., 2016). This zoonotic virus has recently emerged as a recognized cause of fetal infection associated with severe CNS abnormalities, including hydranencephaly and hydrocephalus and, possibly, SIDS (Niklasson et al., 2007, 2009a, 2009b). A study from Sweden identified a strong epidemiologic association between small rodent abundance and the incidence of intrauterine fetal death in humans. Ljungan virus antigen was detected in this study in half of the intrauterine fetal death cases tested (Niklasson et al., 2009b).

Zika Virus

Zika virus is a newly emerging pathogen that has recently been demonstrated to cause serious disease in newborns, most notably microcephaly, in the context of congenital transmission. Congenital infections with related flaviviruses, such as West Nile virus, have been described (Alpert et al., 2003) but are rare (O'Leary et al., 2006; Pridjian et al., 2016). The emergence of Zika virus infection, in contrast, has had a devastating impact on newborn health. Zika virus was first isolated in Uganda in 1947 in rhesus macaques (Dick, 1952; Dick et al., 1952) but received little attention until

early 2015, when an outbreak of Zika virus was identified in northeast Brazil. By late 2015, reports of an increase in the number of infants born with microcephaly in Zika virus-affected areas emerged, and viral nucleic acids were identified in the amniotic fluid of women whose fetuses had been found to have microcephaly (Schuler-Faccini et al., 2016). Since these reports, congenital Zika virus infection has been recognized throughout the Western Hemisphere, including congenital infections identified in the United States (Culjat et al., 2016; Driggers et al., 2016), and this infection has had a devastating impact on newborns. Zika virus infection has been declared a public health emergency of international concern by the World Health Organization (WHO) (Heymann et al., 2016). Although much remains to be learned about Zika virus, it is important for neonatologists and pediatricians to be aware of the clinical manifestations of this emerging neonatal viral infection.

Epidemiology

Zika virus infection was first recognized in Africa, where it was associated with occasional reports of febrile syndromes in humans (MacNamara, 1954) but otherwise was of little clinical significance. Through mechanisms that remain incompletely defined, Zika virus underwent a migration out of Africa into Asia, Micronesia, and the Pacific Islands over the ensuing decades (Haddow et al., 2012), eventually producing outbreaks of disease on the island of Yap (in the Federated States of Micronesia) in the early 2000s (Lanciotti et al., 2008; Duffy et al., 2009) and on Easter Island in 2014 (Tognarelli et al., 2016). No fetal abnormalities were identified initially during a French Polynesia outbreak described in 2013 to 2014, but a retrospective analysis of this outbreak identified 19 cases of congenital cerebral malformations, including septal and callosal disruption, ventriculomegaly, neuronal migration defects, cerebellar hypoplasia, occipital pseudocysts, and brain calcifications (Besnard et al., 2016). Thus it was clear even before the Brazilian outbreak that congenital Zika virus infection could cause major brain malformations.

The extent of the Zika virus epidemic in the Americas as of mid-2016 indicated that virtually all countries in South America had identified active Zika virus transmission, with approximately 50 countries on the official CDC Zika virus travel advisory list (<http://www.cdc.gov/zika/geo/active-countries.html>). Most cases have been identified in Brazil, where in 2015, there were an estimated 440,000 to 1,300,000 Zika virus cases, with approximately 5000 suspected cases of microcephaly, most of them in the northeast region of the country, and an estimated 76 deaths (Heukelbach et al., 2016). Estimates of the total number of cases of brain injury caused by congenital Zika virus infection have been complicated by the lack of a uniform definition of microcephaly (Nunes et al., 2016). In the United States, cases are tracked by the CDC (<http://www.cdc.gov/zika/geo/united-states.html>). As of early 2017, more than 5000 cases of documented Zika virus infection had been reported in US states and territories, and more than 1500 of these have been in pregnant women.

Zika virus infection is predominantly a vector-borne infection, transmitted by the mosquitoes *Aedes aegyptii* and *Aedes albopictus* (Rabaan et al., 2017). Both of these mosquitoes are endemic in the United States (Hahn et al., 2016). Nonvector modes of transmission, particularly sexual transmission, are known to occur (Atkinson et al., 2016; Grischott et al., 2016; Matheron et al., 2016) but appear rare. Zika virus infection has also been documented to be transmitted by blood transfusion (Barjas-Castro et al.,

2016). Autochthonous transmission to humans by mosquitoes has been documented in the United States (in Florida) as of mid-2016.

Pathogenesis

Zika virus is a member of the family *Flaviviridae* (Faye et al., 2014). This family includes West Nile virus, chikungunya virus, yellow fever virus, and dengue virus. Zika virus is an enveloped, positive-sense, single-stranded RNA virus with a genome of approximately 10,800 bases in length. The RNA serves as a single messenger RNA species that encodes a polyprotein that is subsequently cleaved into capsid, precursor membrane (pRM), envelope (E), and nonstructural (NS) proteins. The E protein composes the majority of the virion surface and is involved in aspects of replication, including binding to target receptors and membrane fusion. The E protein is also a candidate subunit vaccine target. The NS1 protein has emerged as a potential diagnostic marker of early infection and a possible vaccine candidate (Rastogi et al., 2016).

Zika virus appears to reach the developing fetus via a transplacental route of transmission. Viral RNA has been identified in amniotic fluid (Calvet et al., 2016), and viral antigens have been identified in fetal brain tissue and placenta/chorionic villi (Martines et al., 2016). Viral particles have also been identified in fetal brain by electron microscopy in the setting of primary maternal infection with associated fetal transmission during pregnancy (Mlakar et al., 2016). The likelihood of microcephaly and associated brain anomalies depends on the timing of infection.

The mechanism of brain injury induced by Zika virus appears to involve direct infection of human neural progenitor cells in the developing fetal brain. These cells, derived from induced pluripotent stem cells, undergo lytic infection and release infectious progeny virus. Both direct virus-mediated cell death and dysregulation of cell cycle progression contribute to brain injury (Tang et al., 2016), as does a virus-induced alteration of immune response and apoptotic gene transcription (Li et al., 2016). Zika virus also interferes with fetal neuronal stem cell differentiation (McGrath et al., 2017; van den Pol et al., 2017). The candidate viral receptor, AXL, is expressed in glial cells, astrocytes, endothelial cells, and microglia in the developing human cortex and in progenitor cells in developing retina (Nowakowski et al., 2016).

Clinical Manifestations

Only one in five infected individuals have symptoms in the setting of primary infection. Symptomatic acute Zika virus infection in the nonpregnant individual produces headache, arthralgia, myalgia, nonpurulent conjunctivitis, erythematous (and often pruritus) rash, and lower back pain (Brasil et al., 2016). Fever, when present, is of low intensity and short lived. Symptoms usually begin within 2 weeks of exposure, and viremia persists for approximately 1 week. Zika virus has also been causally associated with Guillain-Barré syndrome (GBS) (Cao-Lormeau et al., 2016). The antiglycolipid IgG antibodies commonly detected in GBS were detected in less than 50% of cases in one investigation, suggesting a role for direct viral neurotoxicity rather than indirect (immune-mediated) pathogenesis for some patients. Nerve conduction studies demonstrated the acute motor axonal neuropathy type of GBS, and clinical improvement during convalescence suggested a reversible conduction failure component (Cao-Lormeau et al., 2016).

For the congenitally infected fetus, vertical transmission of Zika virus is primarily associated with clinical manifestations related to the CNS. Microcephaly is the prominent potential consequence

of congenital Zika virus infection early in pregnancy. The risk of microcephaly is very much dependent on the trimester of infection, with estimated rates of 0.88%–13.2% following first-trimester infection (Johansson et al., 2016). Although microcephaly has not been reported in the offspring of women infected in the third trimester (Brasil et al., 2016), the brain and placenta can still become infected, and clinical manifestations in infants congenitally infected during this trimester include stillbirth, growth restriction, and EEG abnormalities with motor and tone abnormalities. Other CNS abnormalities include ventriculomegaly, global hypoglyria, and hydranencephaly (Besnard et al., 2016; Hazin et al., 2016; Sarno et al., 2016). Ocular manifestations are common, may occur in the absence of microcephaly, and include pigmentary and hemorrhagic retinopathy, chorioretinal atrophy, abnormal vascular development, optic nerve abnormalities, microphthalmia, and cataracts (de Paula Freitas et al., 2016; Ventura et al., 2016a, 2016b). Hearing loss is described in congenital Zika virus infection (de Barros Miranda-Filho et al., 2016). A case of hydrops fetalis has also been observed (Sarno et al., 2016).

Laboratory Evaluation and Diagnostic Studies

Laboratory abnormalities in the setting of acute Zika virus infection are often nonspecific and may include leukopenia, thrombocytopenia, and transaminitis (Musso and Gubler, 2016). Laboratory diagnosis of Zika virus infection relies on detection of Zika virus-specific RNA by RT-PCR of serum and/or urine. Samples should be obtained within 7 days of symptom onset for suspected cases. Serum PCR results are positive only for a brief window (3–7 days), when the infected individual has viremia; hence a negative result cannot exclude infection. Since urine PCR results may be positive for up to 14 days following onset of symptoms, this may be a useful adjunct to diagnosis. For an individual presenting 4 to 7 days after onset of symptoms with a negative Zika virus PCR result, serologic testing should be performed. Serologic testing for the highly related chikungunya, dengue, and West Nile viruses should also be considered. If Zika virus IgM test results are positive, equivocal, or inconclusive, testing for neutralization antibodies using the plaque reduction neutralization test (PRNT) should be performed. A Zika virus-specific PRNT titer greater than 10 should be interpreted as evidence of infection with Zika virus when the PRNT titer for the other flaviviruses tested is less than 10 (Rabe et al., 2016).

Treatment

No specific treatment is available for Zika virus infection, although intense efforts are under way to identify and develop antivirals for this and other flavivirus infections (Makhluף et al., 2016). A recent cell culture screen identified 2'-C-methylated nucleosides as promising lead candidates for further development (Eyer et al., 2016), but none are currently licensed for clinical use. There are currently no recommendations for passive antibody-based immunoprophylaxis for prevention of maternofetal transmission of Zika virus, although recent animal model studies have demonstrated that adoptive transfer of purified IgG from mice and rhesus macaques vaccinated with various investigational Zika pRM/E vaccines confers passive protection against viral challenge (Abbink et al., 2016; Larocca et al., 2016). These observations provide hope that passive immunoprophylaxis strategies might be developed that are capable of protecting the fetus from disease following maternal exposure during pregnancy (Heinz and Stiasny, 2017).

Clinical Evaluation and Prognosis

The long-term outcome of infants with congenital Zika virus infection remains uncertain. The CDC has provided recommendations for the evaluation and long-term follow-up of infants with possible congenital Zika virus infection (Karwowski et al., 2016). Congenital infection is defined as the presence of Zika virus RNA in any sample collected at birth, including amniotic fluid, placenta, umbilical cord, newborn serum, newborn urine, or newborn CSF (Staples et al., 2016). Investigation for congenital infection should also include testing of newborn serum for the presence of Zika virus IgM antibody, with confirmatory PRNT testing. Infants with microcephaly but negative Zika virus diagnostic evaluation findings should be evaluated for other perinatal infections, particularly CMV infection (Schleiss, 2016). Evaluation by a geneticist is also recommended. For infants with positive or inconclusive Zika virus test results, evaluation for neurologic abnormalities, dysmorphic features, hepatosplenomegaly, and rash is recommended. Cranial ultrasonography is recommended, along with ophthalmologic evaluation within 1 month after birth. Evaluation of hearing before hospital discharge or within 1 month after birth is recommended, along with a repeated audiologic evaluation at 6 months of age. Careful evaluation of developmental milestones, as well as head circumference, is recommended through the first year of life. Ongoing consultation with pediatric neurologists, developmental pediatricians, and physical and speech therapists is appropriate if any abnormalities are noted.

Although Zika virus particles have been observed in breast milk (Dupont-Rouzeyrol et al., 2016), there have to date been no reports of Zika virus transmission by breastfeeding. Currently there is no contraindication to breastfeeding in infants born to women with Zika virus infection, since the theoretical risk of Zika virus transmission through breast milk is outweighed by the known benefits of breastfeeding. Moreover, no developmental complications have been observed in otherwise healthy children with postnatal Zika virus infection or exposure.

Prevention

Avoidance of travel to high-risk areas currently is the only prevention strategy for men and women of reproductive age. If travel is unavoidable, the CDC recommends use of an FDA-approved insect repellent containing *N,N*-Diethyl-*meta*-toluamide (DEET), picaridin, oil-of-lemon eucalyptus, *para*-methane diol, or IR3535. The WHO currently recommends that individuals practice 8-week abstinence or safe sex precautions after return from Zika virus–endemic regions (McCarthy, 2016). However, late sexual transmission because of longer periods of persistence of Zika virus in semen has been described (Turmel et al., 2016). For this reason, couples in whom a man had confirmed Zika virus infection or clinical illness consistent with Zika virus disease should wait at least 6 months after symptom onset to attempt conception.

Vaccines targeting the Zika virus pRM/E protein have been shown to be effective at preventing disease and blocking transmission in mouse and primate models (Larocca et al., 2016; Barouch et al., 2017). Insect vector control is also a critical component of prevention. Proposed interventions include increased use of larvicides (Faraji and Unlu, 2016) and the intentional environmental release of genetically modified mosquitoes incapable of producing progeny after mating (Adalja et al., 2016). Safeguards to protect the blood supply against the potential risk of transfusion-associated Zika virus infections will also need to be developed and implemented (Katz and Rossmann, 2017).

Hepatitis Viruses

There are six distinct viruses known to cause viral hepatitis—hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D (delta agent) virus, hepatitis E virus, and hepatitis G virus (HGV). HGV is of importance for the pregnant patient, but only HBV and HCV are of major importance in the newborn. The main features of each virus type are listed in Table 37.3 (Krugman, 1992; Jonas, 2000; Koff, 2007). HAV is passed by fecal–oral transmission and is a rare cause of neonatal disease, although it has been nosocomially transmitted in the setting of a NICU. Hepatitis E virus is similar to HAV in its mode of transmission and clinical manifestations, except for an increased mortality in pregnant women infected with hepatitis E virus (Aggarwal et al., 2009; Teshale et al., 2010). There are no data regarding perinatal transmission of hepatitis E virus. Hepatitis D virus may cause only coinfection or superinfection with HBV. Its only clinical significance is that HBV infection may become more severe when hepatitis D virus is present. Perinatal transmission has been described (Ramia and Bahakim, 1988) but is uncommon.

HGV, also known as *GB virus type C*, has been associated with acute and chronic hepatitis, and HGV infection is usually noted as a coinfection with HBV or HCV. This virus has a tropism for lymphocytes and may influence the course and prognosis in HIV-seropositive patients (Reshetnyak et al., 2008). Perinatal transmission can occur in 60%–80% of infants born to HGV-viremic mothers, but there has been no report of clinical hepatitis attributed to HGV infection in this setting (Zanetti et al., 1998; Wejstal et al., 1999; Zuin et al., 1999; Ohto et al., 2000). The clinical significance and effects of HGV infection are still poorly understood. HBV and HCV are both transmitted vertically and, among the viral hepatitis, are of the greatest importance to the care of newborns.

Hepatitis B Virus

The issues that are most important to neonatologists are the frequency with which HBV is transmitted to neonates at the time of birth, the short-term and long-term consequences of these infections, the importance of greater surveillance for maternal carriage of HBV, the role of antiviral therapy to prevent transmission and disease progression, and the availability of effective HBV immunoprophylaxis (Krugman, 1988; Arfaoui et al., 2010; Clemente and Vajro, 2016).

Incidence

In certain parts of the world and among certain ethnic groups, as many as 7%–10% of all infants acquire HBV infections at the time of birth, and almost all of these infections become chronic. In the United States, it has been estimated that approximately 20,000 infants are born annually to mothers who are chronic HBV carriers (Mast et al., 1998). Since 1990 the incidence of acute HBV infection in the United States has declined dramatically, with the largest declines occurring in children younger than 15 years (98%) and in young adults aged 15 to 24 years (90%). The frequency of transmission depends primarily on the prevalence of the HBV carrier state among women of childbearing age. HBV is a carcinogenic virus, and infections acquired perinatally can lead to chronic liver failure and hepatic carcinoma in adult life (Beasley and Hwang, 1984; Balistreri, 1988; Chan and Sung, 2006).

The incidence of neonatal HBV infection depends on the timing of infection and the overall prevalence of the disease in the

TABLE 37.3 Viral Hepatitis Types A, B, C, D, E, and G: Comparison of Clinical, Epidemiologic, Immunologic, and Therapeutic Features

| Feature | Hepatitis A | Hepatitis B | Hepatitis C | Hepatitis D | Hepatitis E | Hepatitis G |

From Saul Krugman. Viral Hepatitis: A, B, C, D and E—Infection, *Pediatrics in Review* Jun 1992;13(6):203–212; DOI: 10.1542/pir.13-6-203.

population under study. Women with acute HBV infection during the first or second trimester rarely transmit the virus to their infants (Krugman, 1988; Stevens, 1994). Transplacental transfer has been described but appears to be rare. The carriage rate for hepatitis B surface antigen (HBsAg) ranges from 0.1% in the United States and Europe to 15% in Taiwan and parts of Africa, with intermediate rates in Japan, South America, and Southeast Asia. Transmission rates among immigrant women in Western countries appear to parallel the rates in their countries of origin (Krugman, 1988).

The most important route of transmission is transmission that occurs during labor and delivery. The likelihood of transmission is great if symptomatic acute disease is present (60%–70% transmission; Gerety and Schweitzer, 1977). Infants of hepatitis B e antigen (HBeAg)-positive mothers have an 80%–90% chance of becoming HBsAg carriers (Okada et al., 1976; Lee et al., 1978). The risk of an infant acquiring HBV infection if born to an HBsAg-positive but HBeAg-negative mother is 5%–20%. Chronic neonatal infection occurs in less than 10% of infants of HBeAg-negative mothers (Krugman, 1988). Although HBsAg has been found in breast milk, breastfeeding does not appear to have any influence on the rate of transmission (Beasley et al., 1975). The WHO currently recommends that all mothers who are hepatitis B–positive breastfeed their infants and that their infants be immunized at birth.

Etiology and Pathogenesis

HBV is a DNA virus that localizes primarily in hepatic parenchymal cells but circulates in the bloodstream, along with several subviral

antigens, for periods ranging from a few days to many years. Several distinct genotypes have been identified, and these subtypes show biologic variability in transmission and disease progression (Magnius and Norder, 1995; Schaefer et al., 2009; Kramvis, 2016). Transplacental leakage of HBeAg-positive maternal blood is a potential source of intrauterine infection (Lin et al., 1987). During either acute or persistent viremia in the mother, the virus itself or viral antigens may rarely cross the placenta and cause intrauterine infection, but more commonly infection occurs perinatally during labor or delivery (Chisari and Ferrari, 1995; Xu et al., 2001). The finding of hepatitis virus antigens in the newborn might not indicate the presence of infection but rather might indicate the passive transfer of antigen only; therefore antigen test results should be interpreted cautiously in this setting. HBV infection of placental trophoblast has been documented (Bai et al., 2007). Innate immune responses in the trophoblast appear to play a key role in defense against transplacental transmission, particularly Toll-like receptors 7 and 8 (Tian et al., 2015). Immunoglobulin against HBV also plays a role in prevention of transmission at the placental level, because of antibody deposition in Hofbauer cells that serves as an immune barrier to transmission between the mother and the fetus (Liu et al., 2015). HBeAg plays a role in immune tolerance to infection in the newborn. HBeAg is the only HBV antigen to cross the placenta, and its presence leads to specific unresponsiveness of helper T cells to the viral capsid protein in the newborn (Kramvis, 2016). HBeAg is tolerated in utero, acts as a tolerogen after birth, and its presence in maternal serum is a biomarker for an increased

risk of perinatal transmission. Most infants born to mothers infected with HBV have a negative test result for HBsAg at birth but in the absence of prophylaxis are at risk of becoming HBsAg-positive during the first 3 months of life, suggesting that transmission is primarily peripartum and not transplacental (Krugman, 1988, 1992; Shapiro, 1993; Mulligan and Stiehm, 1994). Prevention of peripartum HBV transmission is not considered to be an indication for primary caesarean delivery.

Clinical Spectrum and Laboratory Evaluation

Infants with HBV infection do not show clinical or chemical signs of disease at birth. Without immunoprophylaxis the usual pattern is the development of chronic antigenemia with mild and often persistent enzyme level elevations, beginning at 2 to 6 months of age (Mulligan and Stiehm, 1994). Less commonly the infection becomes clinically manifest, with jaundice, fever, hepatomegaly, and anorexia, followed by either recovery or chronic active hepatitis. Rarely, fulminant hepatitis is seen and can be fatal (Delaplane et al., 1983).

Laboratory tests are essential in the diagnosis of HBV infection. Evaluations of serum enzymes and bilirubin reflect the extent of liver damage. Serologic tests identify the virus involved (Krugman, 1988). HBsAg appears early, usually before liver disease is found; it persists in those who become long-term carriers or disappears in the 5% of infants in whom the infection is resolved. HBeAg and anti-HBeAg testing can be used to assess infectivity; although they are not as frequently used for serodiagnosis, they are useful markers of the likelihood of perinatal transmission. Risk factors that increase the likelihood of maternofetal transmission include the magnitude of maternal viral load, presence of HBeAg, and a maternal thalassemia minor genotype (Dunkelberg et al., 2014; Zhang et al., 2014). PCR and other nucleic acid detection techniques are important in confirming diagnosis, assessing viral load, and monitoring the response to therapy.

Prevention

The primary goal of prevention is to prevent chronic HBV infection and chronic liver disease. In the United States, in the past 3 decades a comprehensive immunization strategy (summarized in Table 37.4) has been implemented consisting of four components:

1. Universal immunization of all infants beginning at birth
2. Prevention of perinatal infection through routine screening of all pregnant women and appropriate immunoprophylaxis of infants born to HBsAg-positive women (or women whose HBsAg status is unknown)
3. Routine immunization of children and adolescents who have not been immunized previously
4. Immunization of nonimmunized adults at increased risk of infection

For infants the three-dose vaccination schedule should be initiated in the neonatal period or by 2 months of age (Table 37.4). Four doses are acceptable if a birth dose is given and a combination vaccine is used to complete the series. Vaccination can be delayed until just before hospital discharge in preterm (birthweight <2000 g) infants born to HBsAg-negative mothers.

All infants born to HBsAg-positive women should receive both active and passive immunization within 12 hours of birth. The doses and recommended options for administration of the HBV vaccines that are currently licensed in the United States are provided in Table 37.4 (American Academy of Pediatrics Committee on Infectious Diseases, 2015). If the maternal HBsAg status is unknown, it should be checked immediately, and the infant should receive the first dose of HBV vaccine immediately. Infants born to women who test positive or to women in whom the HBsAg status is unknown should be given hepatitis B immune globulin as soon as possible within 1 week after birth. The highest immunization failure rates have been observed in infants of HBeAg-positive women and those infected in utero (Farmer et al., 1987; Tang et al., 1998). Infants who received hepatitis B immunoglobulin and HBV vaccine at birth, followed by two additional immunizations, should be tested for anti-HBsAg and HBsAg at 9 to 12 months of age or 1 to 2 months after the last dose. This is important because about 5% of such infants develop chronic HBV infection even after optimal immunoprophylaxis. Infants who do not receive the vaccine should be tested as soon as they are identified.

In addition to HBV immunoglobulin and vaccination, oral antiviral therapies in highly viremic women can reduce the risk of transmission of HBV to newborns. The use of telbivudine, lamivudine, and tenofovir appears to be safe in pregnancy, with

TABLE 37.4 Licensed Monovalent and Combination Hepatitis B Vaccines

| Clinical Scenario | MONOVALENT VACCINES | | COMBINATION VACCINES | | |
|---|----------------------------------|---------------------|--------------------------------|-------------------------------|----------------------------------|
| | Recombivax Hepatitis B Dose (μg) | Engerix-B Dose (μg) | Twinrix ^a Dose (μg) | Comvax ^b Dose (μg) | Pediatric ^c Dose (μg) |
| Newborns born to HBsAg-negative mothers and children and adolescents aged <20 years | 5 (0.5 mL) | 10 (0.5 mL) | NA | 5 (0.5 mL) | 10 (0.5 mL) |
| Newborns born to HBsAg-positive mothers ^d | 5 (0.5 mL) | 10 (0.5 mL) | NA | 5 (0.5 mL) | 10 (0.5 mL) |
| Adolescents aged 11 to 15 years | 10 (1 mL) | NA | NA | NA | NA |
| Adults aged >20 years | 10 (1.0 mL) | 20 (1.0 mL) | 20 (1.0 mL) | NA | NA |

^aTwinrix is a combination of Engerix-B (20 μg) and hepatitis A vaccine, licensed for use in people aged 18 years or older in a three-dose series in a 0-, 1-, and 6-month schedule.

^bComvax is a combination of Recombivax HB (5 μg) and *Haemophilus influenzae* type B (PRP-OMP) recommended for use at 2, 4, and 12 to 15 months of age. This vaccine should not be administered at birth, before 6 weeks of age, or after 71 months of age.

^cPediatric is a combination of diphtheria and tetanus toxoids and acellular pertussis (i.e., DTaP), inactivated poliovirus, and hepatitis B (Engerix-B, 10 μg). It is recommended for use at 2, 4, and 6 months of age but should not be administered at birth, before 6 weeks of age, or after 7 years of age.

^dHepatitis B immunoglobulin (0.5 mL) should be administered simultaneously with vaccination.

HBsAg, Hepatitis B surface antigen; NA, not applicable.

no increased adverse maternal or fetal outcome (Brown et al., 2016; Piratvisuth et al., 2016). Recently, a prevention study examined whether the use of tenofovir in women with chronic HBV infection (HBeAg positive) could modify the risk of transmission to the newborn. In a cohort of HBeAg-positive mothers with an HBV DNA level of more than 200,000 international units per milliliter during the third trimester, the rate of mother-to-child transmission was lower among those who received tenofovir therapy than among untreated controls (Pan et al., 2016).

Treatment

Currently, seven antiviral agents have been approved by the FDA for treatment of adults with chronic HBV infection in the United States (Bitton Alaluf and Shlomai, 2016). These agents, categorized as either IFNs (IFN alfa-2b and pegylated IFN alfa-2a) or nucleoside or nucleotide analogues (lamivudine, adefovir, entecavir, tenofovir, telbivudine), are used as monotherapy or in combination. Lamivudine is now considered the first-line therapy in adult patients, eclipsing IFN. Experience with and indications for antiviral therapy for HBV infection in children are limited (Clemente and Vajro, 2016). IFN alfa, lamivudine, and adefovir, a RT inhibitor, were the first drugs approved for treatment of chronic HBV infection in children, but success is widely variable (Kurbegov and Sokol, 2009; Giacchino and Cappelli, 2010). In September 2012, tenofovir was approved by the FDA for use in children with chronic HBV infection aged 12 years or older weighing more than 35 kg. More recently, entecavir was approved in the United States for use in children aged 2 years or older with chronic HBV infection and evidence of active viral replication and disease activity and, with IFN alfa, is emerging as a first-line antiviral regimen for children with HBV infection who are candidates for antiviral therapy (Chang et al., 2016; Jonas et al., 2016).

These antiviral therapies are summarized in Table 37.2. IFN alfa appears to be the most effective (approximately 30% HBeAg seroconversion, 10% HBsAg seroconversion), although benefits are primarily observed in children with ALT levels more than twice the upper limit of normal. The virologic response rates for lamivudine mirror those for IFN alfa (23%–31% HBeAg seroconversion), with easier administration and a more favorable safety profile but lower HBsAg seroconversion (2%–3%) and high rates of drug resistance. A 5-year study of entecavir in children demonstrated an HBV DNA negativity rate of 89%–98% at 1 to 5 years of follow-up and an HBeAg seroconversion rate of 18.2% at 5 years; resistance was rare (<1%) (Ray, 2016). Adefovir demonstrates a favorable safety profile and is less likely to select for resistance than lamivudine, but virologic response was limited to adolescent patients and was lower than that of lamivudine (16% HBeAg seroconversion, <1% HBsAg seroconversion). Most experts recommend “watchful waiting” of children with chronic HBV infection, because current therapies are only modestly effective at best, and evidence of long-term benefit is scant. Young children are often believed to be immune tolerant of HBV infection (i.e., they have viral DNA present in serum but normal transaminase levels and no evidence of active hepatitis). In these children, transaminase levels and viral load should be monitored, but they are not typically considered to be candidates for antiviral therapy.

Prognosis

Most long-term follow-up studies have shown that children vaccinated at birth have high levels of protection until at least 5 years of age. Approximately 5%–10% of infants born to HBeAg-positive mothers become long-term HBV carriers despite combined active

and passive immunoprophylaxis with HBV immunoglobulin and HBV vaccine (Kato et al., 1999). Failure of immunoprophylaxis may be associated with the level of maternal viremia and specific HBV genetic variants (Nguie et al., 1998). Infants who become infected with HBV perinatally have a 90% risk of chronic infection, and 15%–25% of those with chronic infection die of HBV-related liver disease (primarily hepatocellular carcinoma) as adults. There is some evidence that the risk of carcinoma correlates with specific HBV genotypes (Sherman, 2010).

Hepatitis C Virus

In 1989, HCV was found to be the main cause of non-A, non-B, parenterally transmitted hepatitis; subsequently, HCV was found to account for a significant portion of the cases of sporadic acute and chronic hepatitis (Choo et al., 1989; Reyes et al., 1990; Weiss and Persing, 1995). HCV is a small, single-stranded RNA virus that is a member of the family *Flaviviridae*; this family consists primarily of vector-borne infections, such as St. Louis encephalitis virus and West Nile virus. HCV is an exception in this family because it is not transmitted by insect vectors. Seven genotypes are described, with significant biologic differences in regard to disease progression and responsiveness to therapy (Klennerman et al., 2009; Smith et al., 2014). Women with chronic HCV infection are more likely to have premature infants or infants with anomalies (Connell et al., 2011). Vertically transmitted HCV infection in infants has been described (Thomas et al., 1998) but is rare. It is associated with maternal viremia and a high rate of chronic hepatitis in the affected infant, but there is less overall liver injury compared with adult HCV infections (Tovo et al., 2000; El-Guindi, 2016).

Incidence

The seroprevalence for anti-HCV antibody in pregnant women ranges from 0.7% to 4.4% worldwide (Conte et al., 2000). In the United States, seroprevalence of HCV decreased during the 1990s and had remained low and stable until recent years; however, rates were unfortunately noted to increase between 2011 and 2014, particularly among women of childbearing age (Koneru et al., 2016). It is estimated that approximately 4.6 million people in the United States have been infected with HCV and that 3.5 million are currently infected (Edlin et al., 2015). Most HCV infections are in men. Forty percent to 50% of women with HCV have no identified known risk factors for infection (Bortolotti et al., 1998). Estimates from the 1990s suggested that the vertical transmission rate of HCV is approximately 5%–11% in HIV-negative mothers and ranges from 10% to 20% from mothers coinfecting with HIV (Palomba et al., 1996; Polywka et al., 1997; Hillemanns et al., 2000; Tajiri et al., 2001). More recent studies, however, suggest a lower rate of vertical transmission, ranging from 2.7% to 3.6% (Ferrero et al., 2003; Syriopoulou et al., 2005). One study has shown, in a multivariate analysis, that higher risk of vertical transmission is related more to maternal use of injection drugs than to HIV infection itself, although the mechanism for this finding is still unclear (Resti et al., 2002). Maternal viral load, HIV coinfection, prolonged rupture of membranes, fetal exposure to maternal infected blood, and invasive monitoring of the fetus increase the risk of viral transmission, and caesarean delivery and breastfeeding increase the transmission risk in women coinfecting with HCV and HIV (Tosone et al., 2014). The risk of HCV infection from transfused blood after the advent of HCV screening is estimated to be less than 1 in 1 million units transfused.

Etiology and Pathogenesis

HCV is transmitted less efficiently by sexual contact than HBV. Risk factors for HCV infection include transfusion, IV drug use, frequent occupational exposure to blood products, and household or sexual contact with an infected person (Weiss and Persing, 1995). In children, perinatal transmission is the most common route of infection (Mohan et al., 2010). Preparations of IVIG contaminated with HCV were reported between April 1993 and February 1994, but since that time, routine screening for HCV with PCR and application of a viral inactivation process during manufacture have been implemented to reduce the risk of transmission (Schiff, 1994).

Perinatal transmission is the leading cause of childhood HCV infection (Mohan et al., 2010). Transmission of HCV from mother to child is thought to occur either in utero or at the time of delivery. HCV has been shown to productively infect placental trophoblasts in cell culture (Nie et al., 2012), although a direct transplacental route of infection remains unproven. Placental innate immunity mediated by natural killer cell responses may prevent direct transplacental transmission of virus in most cases (Hurtado et al., 2010). Viral genotypes and infection and replication in maternal peripheral blood monocytes can also affect the ability of the virus to infect the fetus or newborn (Zuccotti et al., 1995; Azzari et al., 2000). Perinatal transmission is confined almost always to women with HCV RNA in the peripheral blood detectable by PCR, but all children born to women with anti-HCV antibodies should be tested for HCV. Data regarding the correlation of HCV RNA titer in the mother with the risk of vertical transmission are conflicting, although most studies have reported an association (Lynch-Salamon and Combs, 1992; Ohto et al., 1994; Resti et al., 1998; Conte et al., 2000; Tajiri et al., 2001). Maternal peripheral blood mononuclear cell infection by HCV, membrane rupture of longer than 6 hours before delivery, and procedures exposing the infant to maternal blood infected with HCV during vaginal delivery are associated with an increased risk of transmission (Tosone et al., 2014). Internal fetal monitoring is also a risk factor for transmission (Mast et al., 2005). Maternal coinfection with HCV and HIV, maternal history of IV drug use, and HCV infection of the sexual partner of the mother are also risk factors for transmission (Fiore and Savasi, 2009; Indolfi and Resti, 2009). Transmission rates as high as 25% have been reported in HCV-infected, HIV-positive women. The effect of vaginal delivery versus cesarean delivery on transmission rates is unclear (Paccagnini et al., 1995; Gibb et al., 2000); current recommendations do not support the practice of cesarean delivery in women with HCV infection. Primary infection is asymptomatic in most infants. At least one-quarter of infected children will demonstrate spontaneous viral clearance before 6 years of age. Polymorphisms in the *IL28B* gene, and infection with HCV genotype 3, have been associated with greater chances of spontaneous viral clearance (Tovo et al., 2016). In general, HCV progression is mild or moderate in children with chronic infection who grow regularly, although cases with marked liver fibrosis or hepatic failure have been described.

Transmission of HCV via breast milk has not been demonstrated conclusively, although HCV can be found in breast milk and colostrum (Gurakan et al., 1994; Zimmermann et al., 1995). Studies comparing breastfed and bottle-fed infants born to HCV-infected mothers have not shown a statistically significant difference in vertical transmission (Lin et al., 1995; Resti et al., 1998). However, breastfeeding increases the transmission risk in women coinfecting with HCV and HIV (Tosone et al., 2014). Overall, maternal HCV

infection is not a contraindication to breastfeeding (Mast, 2004); however, it may be prudent for mothers who are infected with HCV and who choose to breastfeed to consider abstaining from breastfeeding if their nipples are cracked and bleeding.

Clinical Spectrum and Laboratory Evaluation

Acquired HCV infection typically causes jaundice in one-third of cases and significant increases in ALT in almost all infected individuals. Most neonates perinatally infected with HCV demonstrate little in the way of clinical symptoms; they may have elevated liver ALT levels either transiently or intermittently. The increases in ALT values, when tested, are most commonly noted between 3 and 6 months of age. HCV RNA PCR results may be negative initially at birth or within the first few days of life but typically become positive by 1 to 2 weeks of age and remain so until at least 5 years of age. The highest sensitivity of PCR is reported after 1 month of age (Thomas et al., 1997; Polywka et al., 2006). Confirmatory anti-HCV IgG serology should be delayed until exposed infants are at least 15 to 18 months old, when at least 99% will have cleared maternal antibody (Dunn et al., 2001). Before 18 months of age, only a positive HCV PCR result can confirm the diagnosis of neonatal infection; positive anti-HCV IgG results reflect passively acquired maternal antibody. IgM assays are not available or reliable for perinatal diagnosis of HCV. Liver ultrasonographic findings are usually normal or may consist of a mild diffuse increase in echogenicity. Liver biopsies, when performed in symptomatic children, demonstrate mild to moderate chronic persistent hepatitis (Palomba et al., 1996; Tovo et al., 2000).

Treatment

Until recently, only IFN and ribavirin were approved by the FDA to treat adults and children with chronic HCV infection. The recent development of novel and highly effective antivirals for HCV infection has revolutionized the care of infected patients (Zopf et al., 2016). These drugs are not yet licensed for pediatric use. Novel drugs include ledipasvir, sofosbuvir, daclatasvir, elbasvir, beclabuvir, grazoprevir, paritaprevir, ombitasvir, velpatasvir, and dasabuvir. Ledipasvir, ombitasvir, daclatasvir, elbasvir, and velpatasvir inhibit the virally encoded phosphoprotein nonstructural protein 5A (NS5A), which is involved in viral replication, assembly, and secretion, while sofosbuvir is metabolized to a uridine triphosphate mimic, which functions as an RNA chain terminator when incorporated into the nascent RNA by the NS5B polymerase. Dasabuvir and beclabuvir are also NS5B inhibitors. Paritaprevir and grazoprevir inhibit the nonstructural protein 3 (NS3/4) serine protease, a viral nonstructural protein that is the 70-kDa cleavage product of the HCV polyprotein.

Efforts to treat HCV before the advent of new, “direct” therapy (Zopf et al., 2016) yielded mixed results. Whereas only 10%–25% of adults treated with IFN had a sustained remission of disease (Bonkovsky and Woolley, 1999) treatment with a combination of IFN and ribavirin achieves remission in closer to half of treated adults (Cornberg et al., 2002). Randomized controlled trials indicated that patients treated with pegylated IFNs (so called because they are formulated and stabilized with polyethylene glycol), both as dual therapy with ribavirin and as monotherapy, experienced higher sustained viral response rates than those treated with nonpegylated IFN (Shepherd et al., 2004). The advent of new, direct therapy has led to permanent remission in adult patients. Data on the use of these agents in infants and children are limited, and none are currently approved for pediatric use. The use of IFN alfa-2b in combination with ribavirin has been approved by the

FDA (Palumbo, 2009). In a case series of four pediatric patients treated with IFN for 1 year, viral load decreased to undetectable levels during treatment in all four patients, but two patients became viremic again once the treatment was stopped (Tovo et al., 2000). There are significant genotype-dependent differences in responsiveness to antiviral therapy; patients with genotype 1 had the lowest levels of sustained virologic response, and patients with genotype 2 or 3 had the highest (Shepherd et al., 2004; Palumbo, 2009). The use of IFN alfa-2b in combination with ribavirin provides a much more favorable sustained virologic response in children with HCV genotype 2 or 3 (84%) than in those with HCV genotype 1 (36%; González-Peralta et al., 2005). For genotype 1 HCV infection treated with pegylated IFNs combined with ribavirin, it has been shown that genetic polymorphisms near the human *IL28B* gene, encoding IFN lambda 3, are associated with significant differences in response to the treatment (Ge et al., 2009; Thomas et al., 2009). Older IFN therapies were available only in parenteral formulations and are associated with significant side effects; therefore experience in children has been minimal.

Infants and children with persistent elevations in liver transaminase levels should be referred to a pediatric gastroenterologist for evaluation and treatment. The necessity for as well as the frequency of screening tests of liver function has not been established.

Prognosis

In 60%–80% of HCV-infected adults, chronic hepatitis occurs, and in one-third of HCV-infected adults, chronic HCV infection leads to cirrhosis or liver failure within 20 to 30 years after infection (Iwarson et al., 1995; Leone and Rizzetto, 2010). In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2%–5% per year. There are limited data regarding long-term follow-up in HCV-infected infants, but existing knowledge indicates that most children remain viremic until at least 5 to 6 years of age, and most children who do not achieve spontaneous viral clearance in early life will develop chronic, persistent hepatitis. Studies monitoring infected children beyond 6 years of age have not been completed, but they are at risk of cirrhosis and hepatocellular carcinoma. Transient HCV viremia with subsequent resolution has been reported (Zanetti et al., 1995; Padula et al., 1999; Ruiz-Extremiera et al., 2000). All of the infants who have been followed up for an average of 3 to 4 years have been reported to have normal growth and development (Tovo et al., 2000).

Prevention

Although development of a HCV vaccine is considered to be a major public health priority (Houghton and Abrignani, 2005), currently no vaccine is available. Some experts have noted that, given the safety and effectiveness of new HCV therapies, a vaccine may not be necessary (Stone et al., 2016), although as noted these drugs are not yet available for infants and children. Like all other infants, infants with HCV should receive routine HBV immunization. In addition, they should receive HAV vaccination at 2 years of age. Parents should be advised to avoid unnecessary administration of medicines known to be hepatotoxic. Standard precautions are recommended for the hospitalized infant.

Adenovirus

Adenoviruses are so named because they were originally recovered from human adenoidal tissue; they are medium-sized (90–100 nm), nonenveloped icosahedral viruses composed of a nucleocapsid and

a double-stranded linear DNA genome. They are the largest of the nonenveloped viruses. There are 53 described adenovirus serotypes in humans.

Epidemiology and Clinical Manifestations

Adenoviruses are responsible for a wide variety of clinical syndromes, including conjunctivitis, respiratory tract disease, and gastroenteritis. Adenoviruses cause 5%–10% of upper respiratory tract infections in children and many infections in adults as well. They are a common problem in solid organ and hematopoietic stem cell transplant recipients. No clear seasonality has been described for adenovirus infections.

Adenovirus Infections in Newborns

There are a limited number of reports of adenovirus infection in young infants, but published case series indicate that adenovirus can cause serious, life-threatening disease in the neonate. A review of neonatal adenovirus infection (Abzug and Levin, 1991) identified several characteristic historical features, including prolonged rupture of membranes, history of maternal illness, vaginal mode of delivery, and onset of illness within the first 10 days of life. Serotypes 2, 3, 7, 11, 13, 19, 21, 30, and 35 have been implicated (Andiman et al., 1977; Sun and Duara, 1985; Matsuoka et al., 1990; Abzug and Levin, 1991; Pinto et al., 1992; Osamura et al., 1993). Clinical findings in various case reports and case series have included lethargy, fever or hypothermia, anorexia, apnea, hepatomegaly, bleeding, and progressive pneumonia (Fig. 37.6). Laboratory abnormalities include thrombocytopenia, coagulopathy, and hepatitis. Acquisition

• **Fig. 37.6** Postmortem histologic analysis from a newborn who died of disseminated adenovirus infection at 2 weeks of age. Hematoxylin and eosin stain of lung demonstrating inflammatory infiltrates (arrow) and intranuclear inclusions (arrowhead). This infant had a viral sepsis syndrome characterized by hepatic failure, disseminated intravascular coagulation, and pneumonitis from adenovirus infection presumed to have been acquired intrapartum.

of infection from the mother via vaginal delivery is the presumed mode of transmission in most cases, although transplacental spread has also been implicated.

Although most neonatal adenovirus infections are believed to be acquired in the birth canal, congenital infections have been described, presumably because of transplacental transmission. A wide range of fetal diseases, including pleural effusion, hepatitis, myocarditis, meningitis, and CNS abnormalities, have been described (Meyer et al., 1985; Rieger-Fackeldey et al., 2000; Baschat et al., 2003; Piedra, 2005). The use of steroids and the presence of bronchopulmonary dysplasia appear to increase the risk of adenoviral pneumonia (Faden et al., 2005) in the NICU setting. Disseminated adenovirus infection in neonates younger than 14 days old was noted in a retrospective review to carry a nearly 50% risk of death (Kelley, 2010; Ronchi et al., 2014a). Adenovirus has been implicated as a potential cause of chorioamnionitis and premature birth (Van den Veyver et al., 1998; Tsekoura et al., 2010). Neonatal group C adenovirus infection has also been hypothesized to play an etiologic role in the pathogenesis of childhood leukemia (Gustafsson et al., 2007; Vasconcelos et al., 2008; Ornelles et al., 2015), although this association remains speculative.

Prevention and Intervention

IV ribavirin therapy has been administered to a neonate with disseminated adenovirus infection undergoing extracorporeal membrane oxygenation, with evidence of viral clearance noted within 48 hours of initiation of therapy (Aebi et al., 1997). Adenovirus vaccines were at one time available for use in military personnel (Gaydos and Gaydos, 1995; Tucker et al., 2008) but are not currently in production. Adenoviruses are hardy and resistant to inactivation by physical and chemical methods that kill most viruses, adding to the challenge of hospital infection control during outbreaks of infection. Nosocomial outbreaks in NICUs have been described in association with ophthalmologic procedures (Calkavur et al., 2012) and by healthcare worker-mediated transmission (Henquell et al., 2009). Although cidofovir has not been approved by the FDA for pediatric use, it has been noted to be an effective antiviral agent for adenovirus infections (Ganapathi et al., 2016), although experience with the use of this agent in newborns is very limited.

Respiratory Viruses

Although relatively uncommon, any one of the respiratory viruses can cause symptomatic respiratory disease in newborns. The association has been described for rhinoviruses, adenoviruses, parainfluenza viruses, influenza virus, and RSV (Kujari et al., 2014; Ronchi et al., 2014b). Adenovirus, rhinovirus, and parainfluenza virus infections are generally characterized by mild rhinorrhea in neonates. All of these viruses, however, can cause clinical symptoms indistinguishable from those of bacterial infection, leading to increased diagnostic testing and empiric antibiotic treatment. Influenza virus infections are usually mild, but in the absence of maternally transmitted antibody, they can be life threatening, with severe pneumonia, hypoxia, and a prolonged course. During the H1N1 influenza pandemic of 2009 to 2010, pregnant women were at a uniquely high risk of severe influenza (Jamieson et al., 2009), and infections were described in neonates (Sert et al., 2010).

The most extensive nursery outbreaks of viral respiratory disease, however, have been caused by RSV (Hall et al., 1979; Wilson et al., 1989). Because of the importance that RSV plays in the newborn nursery, this virus is considered in greater detail in the following section.

Respiratory Syncytial Virus

RSV is the major cause of viral pneumonia and bronchiolitis in infants and children. In temperate climates it causes large annual epidemics during the winter and early spring months (typically ranging from November through April). During these months, RSV appears to be responsible for up to 20% of all pediatric hospital admissions (Hall et al., 2009). Nosocomial infections are frequent during these times, and illness among hospital staff members is a major factor in its spread from infant to infant. Several nursery outbreaks have been described. In one of these outbreaks, cultures were obtained prospectively so that a full picture of the virus's pathogenicity and epidemiology could be drawn (Hall et al., 1979). Twenty-three of 66 infants hospitalized for 6 days or more were infected. Virtually all infants were symptomatic. Clinical manifestations included pneumonia, upper respiratory tract infection, apneic spells, and nonspecific signs. Pneumonia and apnea were seen almost exclusively in infants older than 3 weeks, and nonspecific signs were most commonly observed in younger infants. Four infants (17%) died, two unexpectedly, during the course of infection. The spread of infection in the unit was difficult to interrupt; infants in incubators did not seem to be protected against acquisition of the infection. Eighteen of the 53 nursery personnel were infected during the outbreak; 83% of the infected nursery providers were symptomatic. Of particular importance is the observation that RSV infection, both in term infants and in preterm infants, is commonly associated with a new onset of apnea (Bruhn et al., 1977). Boys are at greater risk than girls of serious RSV disease. RSV-associated apnea has been the probable explanation for some case reports of deaths attributed to SIDS (Eisenhut, 2006). RSV lower respiratory tract disease can be slow to resolve. After discharge from initial hospitalization, risk factors for infant rehospitalization secondary to RSV infection include premature gestational age, chronic lung disease, siblings in day care or school, chronologic age of less than 3 months, and exposure to tobacco smoke (Carbonell-Estrany and Quero, 2001).

Diagnosis can be confirmed by DFA staining of nasopharyngeal or tracheal aspirate, nasopharyngeal swab, or other respiratory secretions. Culture of RSV can require 3 to 5 days and can be used if DFA staining is not available. PCR is also available for the rapid diagnosis of infection and is rapidly emerging as the preferred diagnostic study for RSV infection, commonly performed as a component of a "multiplex" assay that simultaneously tests for multiple viral pathogens (El Kholy et al., 2016).

Treatment and prevention of RSV infections in infants attracted considerable attention during the 1990s because of the clinical and economic impacts of these infections (Groothuis, 1994; Levin, 1994; Meissner, 1994; Kinney et al., 1995). Considerable debate has ensued concerning the efficacy, safety, and potential effect on healthcare workers of ribavirin therapy, so its use remains controversial (Wald and Dashefsky, 1994; Meissner, 2001; Ventre and Randolph, 2004). Treatment consists of nebulization of ribavirin by a small-particle aerosol generator supplied by the manufacturer into an oxygen hood, tent, or mask from a solution containing 20 mg of ribavirin per milliliter of water (Table 37.2). The aerosol has been administered on various schedules for 3 to 5 days (e.g., 12 to 20 hours per day). The efficacy of ribavirin in this setting remains unclear. Some long-term benefit with regard to recurrent wheezing may be realized (Ventre and Randolph, 2004). Corticosteroids are not effective in the treatment of RSV infection.

Prevention efforts have focused on passive and active immunization. Standard IVIG therapy has not been shown to be efficacious

• BOX 37.4 Guidelines for Prophylaxis in Preterm Infants at the Start of the Respiratory Syncytial Virus Season

- Infants born at ≤ 29 weeks' gestation who are younger than 12 months at the start of the respiratory syncytial virus (RSV) season (Monthly prophylaxis should be discontinued if an infant is hospitalized with documented RSV disease.)
- In the first year of life, palivizumab is recommended for premature infants with chronic lung disease of prematurity, defined as birth at < 32 weeks' gestation and a requirement for more than 21% oxygen for at least 28 days after birth.
- Clinicians may administer palivizumab prophylaxis in the first year of life to certain infants with hemodynamically significant heart disease (consultation with a pediatric cardiologist is recommended).
- Clinicians may administer up to a maximum of five monthly doses of palivizumab (15 mg/kg per dose) during the RSV season to infants who qualify for prophylaxis in the first year of life (monthly prophylaxis should be discontinued if an infant is hospitalized with documented RSV disease).
- Palivizumab is not recommended in the second year of life except for children with chronic lung disease of prematurity who continue to require medical interventions such as supplemental oxygen, diuretics, and/or corticosteroids.
- Palivizumab may be considered in infants with pulmonary abnormalities, neuromuscular diseases, or profoundly immunocompromised states (including heart transplant in children younger than 2 years) or in Alaskan Native or other remote Native American populations in which costs associated with medical transport are high.
- Palivizumab therapy is not recommended for children with Down syndrome.

for prevention of RSV infection in high-risk infants (Meissner et al., 1993). The efficacy of monthly prophylactic administration of RSV-specific immunoglobulin (750 mg/kg or 150 mg/kg) in 249 infants with cardiac disease or bronchopulmonary dysplasia was examined in a multicenter trial (Groothuis, 1994). In the high-dose (750 mg/kg) group, there were fewer lower respiratory tract infections, hospitalizations, days in hospital, and days in the intensive care unit as well as less use of ribavirin. Subsequently, a mouse monoclonal antibody was developed, which provides similar protection against RSV (i.e., palivizumab). Unlike anti-RSV immunoglobulin, which is a pooled human blood product, the monoclonal antibody does not confer the theoretical risk of acquiring blood-borne pathogens. Palivizumab is also substantially easier to administer because it is given as an intramuscular injection. Current recommendations by the AAP for the use of palivizumab are summarized in Box 37.4 (Committee on Infectious Diseases and Bronchiolitis Guidelines Committee, 2014). Additional preventive measures for high-risk infants include elimination or minimization of exposure to tobacco smoke, avoidance of crowds and situations in which exposure to infected individuals cannot be controlled, careful hand hygiene education of parents, vaccination against influenza beginning at 6 months of age, and restriction of participation in child care during the RSV season whenever feasible. The prospects for infant or maternal immunization with live attenuated and protein subunit vaccines are under active investigation (Piedra, 2000; Crowe, 2001; Fretzayas and Moustaki, 2010; Saso and Kampmann, 2016). Since RSV produces its most significant morbidity in the newborn, an RSV vaccine may one day ideally be used in pregnant women (Gerds et al., 2016).

Nosocomial spread of RSV and other respiratory viruses can be minimized by emphasis on hand washing by care providers

between contacts with patients. Without additional special precautions, an attack rate of approximately 26% has been observed (Madge et al., 1992). Use of standard contact precautions, such as cohort nursing and the use of gowns and gloves for all contacts with RSV-infected children, can reduce the risk of nosocomial RSV infection to 9.5% (Madge et al., 1992). Palivizumab has been reported to be a useful adjunct in the control of nursery-associated outbreaks of RSV infection (Hammoud et al., 2016).

Gastrointestinal Viruses

Historically, the most important of the viruses that cause diarrhea from the perspective of the neonatal nursery are the rotaviruses. This important group of viruses, with at least four serotypes, is responsible for a large proportion of significant and sometimes severe diarrhea in infants aged 6 to 24 months (Cohen, 1991; Haffee, 1991; Taylor and Echeverria, 1993; Greenberg et al., 1994). Although the overall burden of rotavirus disease has been reduced substantially by the licensure of a number of rotavirus vaccines for use in the routine childhood immunization series (Bernstein, 2009; Dennehy, 2015), rotavirus still continues to produce disease in infants, particularly in parts of the developing world where vaccine is not available. Evidence suggests that rotavirus causes an unexpectedly significant burden of disease in infants as young as 2 to 3 months (Clark et al., 2010). Nursery-acquired infections are common; surprisingly, such infections appear to be benign in most infants. Two studies performed in nurseries in Sydney, Australia, and in London found that 30%–50% of 5-day-old babies shed the virus (Murphy et al., 1977; Chrystie et al., 1978). However, more than 90% of the infected infants were asymptomatic.

Noroviruses are a genetically diverse group of single-stranded, positive-sense RNA, nonenveloped viruses. These viruses belong to the family *Caliciviridae*. The genus *Norovirus* has one species, which is designated as *Norwalk virus*, although there are many serotypes and strains. Outbreaks of norovirus infection have been described in the NICU setting (Tzialla et al., 2011). IUGR infants have been observed to be more likely to shed norovirus and other enteric viruses than infants who are appropriate for gestational age (Naing et al., 2013). Therapy is supportive.

Human Immunodeficiency Virus Infection

Introduction

The HIV epidemic has seen dramatic shifts since the first cases were identified in the early 1980s. Great strides and vast achievements have been made globally in identifying infected individuals, increasing access to treatments, and implementing prevention programs (Royce et al., 1997). The first major breakthrough for mother-to-child transmission came in February 1994 with results of the Pediatric AIDS Clinical Trials Group (PACTG) protocol 076 study (Connor et al., 1994) demonstrating that risk decreased from 25.5%–8.3% when the mother and infant were treated with zidovudine. Now with universal prenatal HIV counseling and testing, antiretroviral (ARV) prophylaxis, scheduled caesarean deliveries, and avoidance of breastfeeding, the rate of mother-to-child transmission has dropped to 2% or less in the United States and Europe.

Still, there is much work to be done. The WHO reported statistics from 2014 showing that 73% of all pregnant women with HIV globally received medicines to prevent transmission to their infants,

and only 32% of HIV-infected children received ARV therapy (ART), compared with 41% of adults. The “Global Plan” was devised in 2010 by a “Global Task Team” consisting of a group of stakeholders from 25 countries and 30 representative international organizations cochaired by Joint United Nations Programme on HIV/AIDS (UNAIDS) and the US government. This plan outlines several steps leading “towards the elimination of new HIV infections among children and keeping their mothers alive by 2015” and prioritizes 22 countries with the highest numbers of pregnant women with HIV. On the basis of the progress report released in 2015, the goals have not yet been reached. The first main goal is to reduce new HIV infections among children by 90% from the benchmark established in 2009. The countries targeted in the Global Plan have collectively reduced new infections by 48% so far. Another main goal is to reduce the mother-to-child transmission rate to 5% or less among breastfeeding groups and to 2% or less among nonbreastfeeding groups. The rates are 28% and 14%, respectively, as last reported from the target countries. This important work will continue until the original goals are met (UNAIDS, 2015a).

The WHO released a guideline in September 2015 stating that “antiretroviral therapy (ART) should be initiated in everyone living with HIV at any age at any CD4 cell count” (World Health Organization, 2015). This caused a significant shift in the global approach, with the new emphasis on treatment for all. With the increasing availability of ARVs globally, children who acquired HIV through the perinatal period or through breastfeeding are living longer and reaching adolescence in record numbers. There are an estimated 2 million adolescents aged 10 to 19 years with HIV globally. However, AIDS is still the leading cause of death among adolescents in Africa and the second leading cause globally. AIDS-related deaths in adolescents have tripled since 2000 while declining among all other age groups (Idele et al., 2014; UNAIDS, 2015b).

Among these adolescents infected via mother-to-child transmission is an emerging group of young women reaching childbearing age. They too are becoming pregnant and delivering their own children, bringing new challenges to prevention efforts. The psychosocial and emotional needs of this group are unique. Some studies suggest higher rates of preterm or small for gestational age births and found that these patients are more likely to have lower median CD4⁺ T lymphocyte counts, detectable viral loads, and genotypic drug resistance (Badell et al., 2013; Munjal et al., 2013).

Prevention of Mother-to-Child Transmission of Human Immunodeficiency Virus

Antepartum

All pregnant women with an unknown HIV status should be tested for HIV with their first routine prenatal screening. The best screening test is an FDA-approved fourth-generation HIV antibody–antigen combination immunoassay. This test detects both HIV-1 and HIV-2 antibodies as well as the HIV-1 p24 antigen. The addition of antigen testing provides a shorter window to detect infection of 2 weeks since initial infection compared with 4 weeks by older-generation Western blot testing. When HIV infection occurs early, the antibody test results may be negative or indeterminate while the antigen test is positive (Centers for Disease Control and Prevention and Association of Public Health Laboratories, 2014).

Women with an initial negative HIV test who are considered to be high risk should be tested again with an HIV antibody–antigen combination test in the third trimester, ideally before their 36th week of gestation. This includes women with a new sexually

transmitted infection, with a known HIV-positive partner, with high-risk HIV-associated behaviors, who are incarcerated, who live in areas with elevated HIV incidence, or who receive care in facilities with an HIV incidence of at least 1 case per 1000 pregnant women per year.

Acute HIV infection during pregnancy (or breastfeeding) poses an increased risk of mother-to-child transmission of HIV because of the rapid development and high levels of HIV viral load. Furthermore, the diagnosis can easily be missed because the acute retroviral syndrome can mimic symptoms of infections with other common viruses such as influenza virus or EBV. These cases represent a significant portion of the transmission still occurring in developed countries such as the United States (Nesheim et al., 2013). Providers must be diligent and quick to test or retest pregnant women who are high risk or who present with a constellation of symptoms suggestive of acute retroviral syndrome such as pharyngitis, lymphadenopathy, myalgia, arthralgia, rash, or fever.

Whenever infection is suspected within less than 2 weeks, the results of antibody testing are unclear, or antigen testing is not available, then a plasma HIV RNA PCR (for viral load) should also be performed in addition to the HIV antibody–antigen combination immunoassay.

Once a pregnant woman has been identified as infected with HIV, ART should be started as soon as possible. Current consensus is that all pregnant women with HIV-1 infection should receive combination ART regardless of the absolute CD4 count or viral load. ARV drug resistance testing should be performed for each pregnant woman who is ARV naive with a viral load of more than 500 to 1000 copies, but ART can be started while the results are awaited and adjusted accordingly later because of the importance of viral load suppression (Drake et al., 2014). Viral resistance testing is important because a woman can acquire a new HIV infection with a resistant strain, irrespective of her antiviral treatment history.

The choice of ARV drug combination is based on many factors, but in general ARV-naïve pregnant women should receive at least three active ARVs. This usually consists of a backbone of two nucleoside/nucleotide RT inhibitors (several options) along with a nonnucleoside RT inhibitor (efavirenz therapy initiated after 8 weeks of pregnancy) or an integrase inhibitor (raltegravir) or a protease inhibitor (several options). If a protease inhibitor is chosen, it should be combined with ritonavir, which is a potent inhibitor of the cytochrome P450 pathway and thus significantly increases the serum concentration of the protease inhibitor. This is known as a *ritonavir-boosted protease inhibitor regimen*. However, it is important to note that known HIV-infected pregnant women currently receiving ART should continue with their combination therapy if it is tolerated and effective at viral suppression.

Generally, the literature is reassuring regarding the rate of birth defects related to ARV teratogenicity. The Pediatric HIV/AIDS Cohort Study overall first-trimester ARV exposure was not associated with an increased risk of birth defects. Because of study findings in nonhuman primates that are largely debated, FDA labeling for efavirenz advises against efavirenz use in pregnancy in the first trimester. Guidelines suggest that treatment with efavirenz should be avoided during the first 8 weeks of pregnancy (the primary period of fetal organogenesis) whenever possible. However, they also note that if a pregnant woman is doing well with efavirenz therapy at presentation, risks and benefits should be weighed given that most pregnant women present to care after organogenesis is already complete (Ford et al., 2011).

The goal of ART is to maintain a viral load below the limit of detection throughout pregnancy. To that end, viral load should

be tested several times during the pregnancy with a plasma HIV RNA PCR. Testing should be performed at the initial visit, 2 to 4 weeks after initiation or change of ART, monthly until viral load is undetectable, and at least every 3 months after suppression is achieved. An additional test must be done in all cases at 34 to 36 weeks' gestation to ensure viral suppression at delivery and to plan for the mode of delivery.

Early ultrasonography is recommended for assessment of gestational age to allow the careful planning of the mode of delivery. Protease inhibitor regimens in general have been associated with an increased risk of hyperglycemia, and so there is a theoretical risk of this increasing in the setting of pregnancy. Most studies have not shown an increased glucose intolerance; however, some experts recommend early and aggressive glucose screening for those women on ARV regimens containing protease inhibitors (Hitti et al., 2007). There is no recommendation or practice for additional glucose screening in the exposed infant.

Guidelines on the prevention of HIV-2 (in contrast to HIV-1) transmission during pregnancy are based largely on expert opinion. Data suggest that the rates of perinatal transmission of HIV-2 are low regardless of intervention (0%–4% reported). As a result, opinions are mixed on whether or not the mothers need to receive ART during pregnancy. Most suggest ARV prophylaxis during pregnancy with use of agents known to be active against HIV-2 and allow discontinuation after delivery if the mother is otherwise well and the absolute CD4 count is greater than 500 (Burgard et al., 2010).

Intrapartum

HIV-1-infected pregnant women who have plasma viral loads with more than 1000 copies/mL or unknown viral loads near the time of delivery should have a scheduled caesarean delivery at 38 weeks. This timing is recommended to decrease the possibility of the onset of labor or rupture of membranes before delivery can occur. Studies in 1999 (both a multicenter randomized controlled trial and a metaanalysis) showed a dramatic decrease in the risk of transmission by 50%–80% when caesarean deliveries were performed at this juncture. The same year, the Women and Infants Transmission Study showed that no viral transmissions to infants occurred when women had viral loads of less than 1000 copies/mL (Garcia et al., 1999). Later studies continued to support the decrease in transmission rates with caesarean delivery, but there are some reports of transmission occurring despite low viral loads, albeit at very low rates. Therefore the decision to deliver vaginally when viral loads are less than 1000 copies/mL should be individualized for each woman and infant by weighing the risks of caesarean delivery overall with the potential benefits.

The original PACTG protocol 076 study administered IV zidovudine therapy to all women with HIV in labor. Now with many women achieving viral suppression with ART, intrapartum therapy is no longer universal. The French Perinatal Cohort group demonstrated that IV zidovudine therapy was not needed for women with HIV RNA loads of less than 1000 copies/mL (Briand et al., 2013), and several other studies were able to duplicate these results. Therefore IV zidovudine therapy should be given to HIV-infected women in labor with HIV RNA loads greater than 1000 copies/mL, but it is not required for HIV-infected women receiving ART who have documented viral loads of less than 1000 copies/mL near delivery. If women have unknown viral loads, they should also receive IV zidovudine therapy. In women who present in labor with unknown HIV status, HIV testing should be expedited, and if the results are positive, a confirmatory test should be done and

IV zidovudine therapy should be started immediately. Ideally, administration should begin 3 hours before delivery or as soon as possible. The dual purpose of the use of zidovudine intrapartum is to reduce the maternal HIV viral load and to provide preexposure and postexposure prophylaxis to the infant against intrapartum transmission. See Fig. 37.7 for a suggested approach for a pregnant woman with unknown HIV status with delivery imminent.

It is still recommended to administer IV zidovudine therapy intrapartum even when the mother's virus has known resistance to zidovudine when the HIV RNA load is greater than 1000 copies/mL near delivery. It is recommended to use 2 mg/kg IV continuous infusion during the first hour and then 1 mg/kg IV continuous infusion each hour thereafter until the cord is clamped. This should begin at least 3 hours before delivery. Any oral ARVs the mother was taking before delivery should continue to be taken. This recommendation is in part due to the understanding that perinatal transmission of resistant virus has been reported but appears to be infrequent. There are some data suggesting that drug resistance mutations that lead to decreased viral fitness may also decrease viral transmissibility (Chen et al., 2011). Furthermore, zidovudine has a long-established track record of reducing the risk of transmission, as discussed previously. Zidovudine also has unique characteristics, including crossing the placenta readily, providing a high maternal-to-cord blood ratio, and penetrating the CNS well.

There is a potential increased risk of transmission with some obstetric procedures, including artificial rupture of membranes, invasive fetal monitoring such as with fetal scalp electrodes, and use of forceps or vacuum-assisted delivery. Episiotomy should also be avoided if possible.

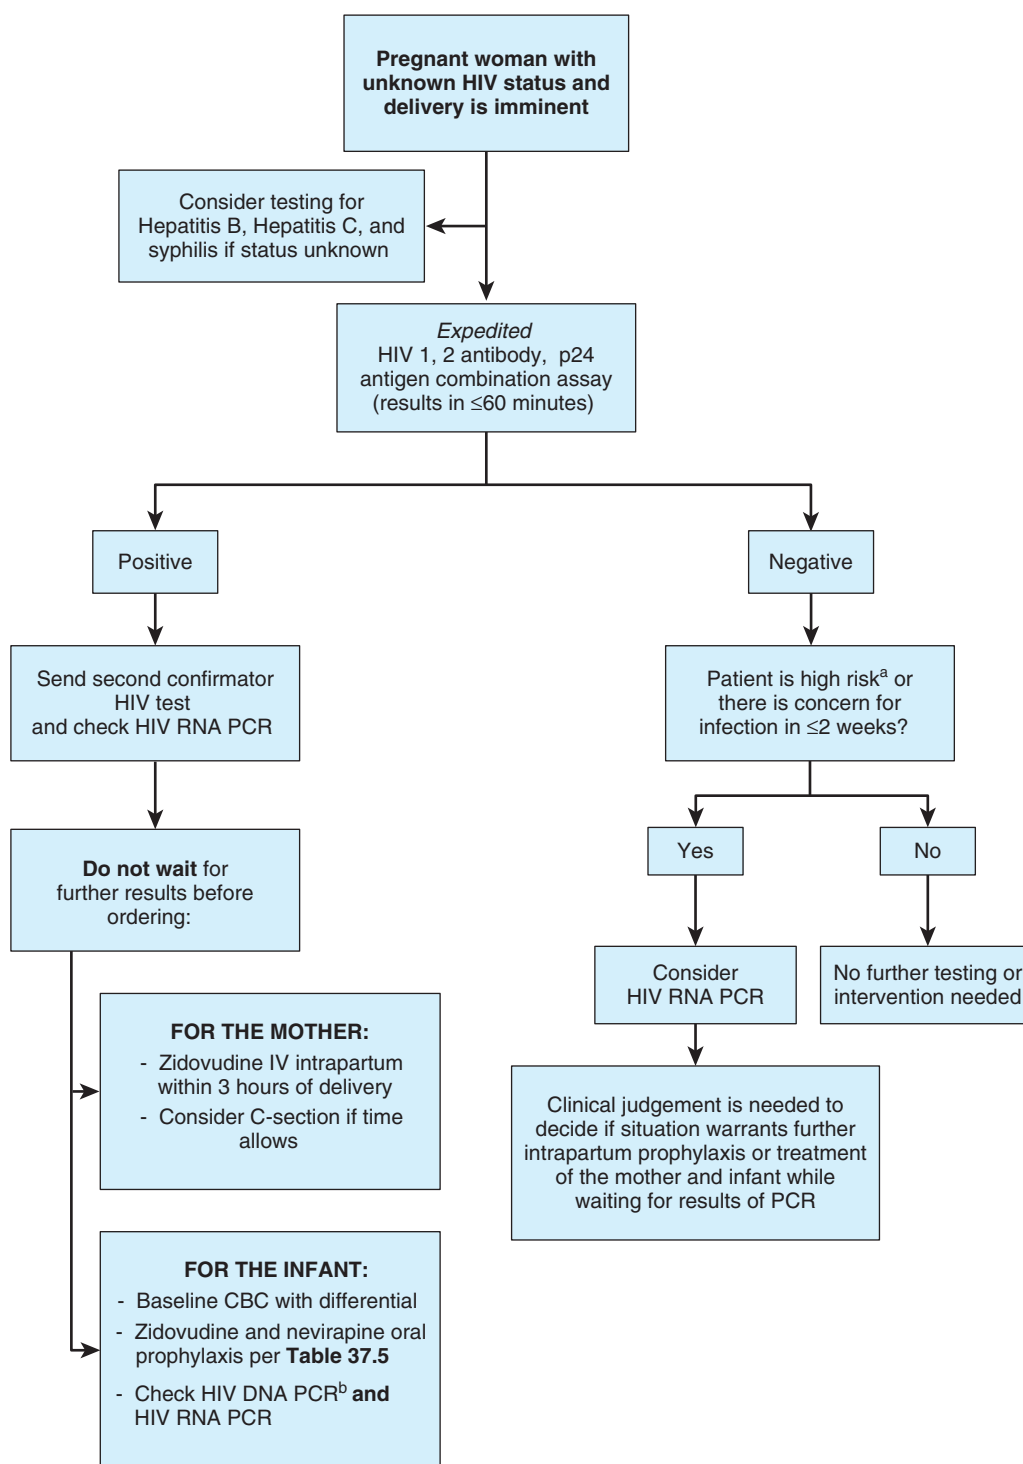

Postpartum

Mothers with HIV-1 infection should continue their ARV regimen after delivery, as ART is now recommended for all HIV-1-infected individuals. The unique challenges of labor, delivery, and motherhood may increase the barriers to adherence, and so the mother should receive any additional support that is needed to continue therapy. Contraception options should be discussed early. As the mother will no longer receive obstetric care after her postpartum visit, careful attention should be made to ensure that she is following up with an HIV care provider and that she has full linkage to care.

All HIV-exposed infants require ART for at least the first 4 to 6 weeks regardless of the mother's viral load at the time of delivery (see the next section).

Breastfeeding by HIV-infected mothers is not recommended in the United States and other developed countries where replacement feeding (formula) is affordable, the water supply is safe, and the risk of infant death due to diarrheal and respiratory infections is low. Infant prophylaxis with ART and maternal postpartum ART cannot completely eliminate the risk of infection. The AAP released a policy statement in 2013 recommending that HIV-infected mothers in the United States not breastfeed their infants, regardless of maternal viral load and ART (Committee on Pediatric AIDS, 2013).

In the developing world where these conditions are not met, many HIV-infected mothers do continue to breastfeed. Several studies of infant prophylaxis with ART and maternal combination ART postpartum were shown to decrease the risk of transmission through breast milk (Bedri et al., 2008). Another study showed that exclusive breastfeeding leads to lower concentrations of HIV in breast milk, while decreases in the frequency of breastfeeding can cause viral levels to increase (Kuhn et al., 2008). In 2010 the

• **Fig. 37.7** Proposed algorithm for treatment of a neonate born to a woman with indeterminate or unknown human immunodeficiency virus (HIV) status. A rapid turnaround time HIV antibody/p24 assay should be performed. In women who present in labor with unknown HIV status, HIV testing should be expedited, and if the results are positive, a confirmatory test should be done and intravenous (IV) zidovudine therapy should be started immediately if the results are positive or the index of suspicion is high. The recommendation is 2 mg/kg IV continuous infusion during the first hour and then 1 mg/kg IV continuous infusion each hour thereafter until the cord is clamped. This should begin at least 3 hours before delivery. Recommendations for empiric therapy of the newborn with zidovudine and nevirapine, pending the results of nucleic acid testing, are outlined in Table 37.5. ^aHigh risk can be defined as a pregnant woman with a new sexually transmitted infection, with a known HIV-positive partner, with high-risk HIV-associated behaviors, who is incarcerated, and/or who lives in an area (or receives care in facilities) with an elevated HIV incidence. ^bIf available. CBC, Complete blood count; C-section, caesarean section; HIV, human immunodeficiency virus; IV, intravenous; RNA, ribonucleic acid; PCR, polymerase chain reaction.

WHO recommended that national authorities in each country decide which infant feeding practice should be promoted in their locality: either complete avoidance of all breastfeeding or exclusive breastfeeding while taking ARVs. However, the ART exposure may be associated with development of ARV drug resistance in infants who become infected despite the prophylaxis (Fogel et al., 2011).

There may be times when an HIV-infected mother breastfeeds inadvertently. There is no guideline as to what to do in this instance, and practice differs. Some experts consider 4 to 6 weeks of post-exposure prophylaxis with ART after the breastfeeding stopped, but this remains controversial.

Another potential mode for mother-to-child transmission is via premasticated food (Ivy et al., 2012). Healthcare providers should be aware of this risk and counsel mothers and other HIV-infected caregivers to avoid this practice.

Treatment of the Human Immunodeficiency Virus–Exposed Infant

All Human Immunodeficiency Virus–Exposed Infants

ARV prophylaxis should be started as soon as possible and ideally within 6 to 12 hours of birth in all HIV-exposed newborns. Oral zidovudine therapy for 6 weeks is still the recommended course based on the PACTG protocol 076 study (Connor et al., 1994). With use of more recent data (Ferguson et al., 2011), guidelines suggest that a 4-week oral zidovudine regimen can be considered in term infants with mothers who had viral suppression throughout pregnancy and adhered to their combination ART; see Table 37.5, which indicates recommended zidovudine dosing based on gestational age, birthweight, and the status of maternal antepartum ARV regimens. A complete blood count with differential should

be performed before zidovudine therapy is started. Thereafter, hematologic monitoring is needed, but there is no specific recommendation as to when to test or how often. Anemia is the primary complication seen in infants with a 4- to 6-week prophylactic zidovudine regimen, and neutropenia also occurs. The PACTG protocol 076 trial showed that zidovudine-exposed infants had lower hemoglobin levels at birth compared with the placebo group. A difference in hemoglobin values persisted throughout the 6 weeks of treatment (Connor et al., 1994). If the infant also had in utero exposure to maternal combination ART, there may be more anemia and/or neutropenia than found in infants exposed to zidovudine alone, as found in the PACTG 316 trial (Dorenbaum et al., 2002). Most experts will check a complete blood count with differential again when they are also drawing blood for a nucleic acid amplification test or if the infant has symptoms of anemia.

Newborns considered to be at higher risk of HIV transmission should have 6 weeks of oral zidovudine therapy and also three doses of nevirapine in the first week of life (Table 37.5). This is at birth, 48 hours later, and 96 hours after the second dose. Higher-risk newborns include those born to mothers who did not receive any antepartum or intrapartum ART and/or mothers with more than 1000 viral copies/mL near delivery and/or mothers whose viral load is unknown. This recommendation is based on data from the National Institute of Child Health and Human Development HIV-1 Prevention Trials Network (NICHD-HPTN) 040/PACTG 1043 study (Nielsen-Saines et al., 2012). Some experts advocate the use of triple ARV prophylaxis in these high-risk infants. However, there are no data demonstrating improved efficacy for a three-drug regimen over a two-drug regimen in the prevention of transmission. The most common regimen is the use of zidovudine, lamivudine, and nevirapine in combination (McKeegan et al., 2011).

TABLE
37.5

Antiretroviral Prophylaxis Dosing for All Human Immunodeficiency Virus–Exposed Infants

| Dosing | | Duration |
|---|--|--|
| Zidovudine | ≥35 weeks' gestation at birth: 4 mg/kg per dose orally twice daily, started as soon after birth as possible and preferably within 6 to 12 h of delivery (or, if unable to tolerate oral agents, 3 mg/kg per dose intravenously, beginning within 6 to 12 h of delivery, then every 12 h) | Start at birth and continue for 4 to 6 weeks ^a |
| Zidovudine | ≥30–<35 weeks' gestation at birth: 2 mg/kg per dose orally (or 1.5 mg/kg per dose intravenously), started as soon after birth as possible, preferably within 6 to 12 h of delivery, then every 12 h, advanced to 3 mg/kg per dose orally (or 2.3 mg/kg per dose intravenously) every 12 h at age 15 days | Start at birth and continue for 6 weeks |
| Zidovudine | <30 weeks' gestation at birth: 2 mg/kg body weight per dose orally (or 1.5 mg/kg per dose intravenously) started as soon after birth as possible, preferably within 6 to 12 h of delivery, then every 12 h, advanced to 3 mg/kg per dose orally (or 2.3 mg/kg per dose intravenously) every 12 h after age 4 weeks | Start at birth and continue for 6 weeks |
| Additional Antiretroviral Prophylaxis Agents for HIV-Exposed Infants of Women WHO Received No Antepartum Antiretroviral Prophylaxis (Initiated as Soon After Delivery as Possible) | | |
| Nevirapine (in addition to zidovudine as shown above) | Birthweight 1.5 to 2 kg: 8 mg per dose orally Birthweight >2 kg: 12 mg per dose orally | Three doses in the first week of life: 1. Within 48 h of birth 2. 48 h after first dose 3. 96 h after second dose |

^aA 6-week course of neonatal zidovudine therapy is generally recommended. A 4-week neonatal zidovudine prophylaxis regimen may be considered when the mother has received standard antiretroviral therapy during pregnancy with consistent viral suppression and there are no concerns related to maternal adherence.

HIV, Human immunodeficiency virus.

Modified from Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission. Recommendations for use of antiretroviral drugs in pregnant HIV-1 infected women for maternal health and interventions to reduce perinatal HIV transmission in the United States. <http://aidsinfo.nih.gov/contentfiles/lvguidelines/PerinatalGL.pdf>; 2016.

All HIV-exposed newborns should be tested for HIV infection at the baseline (usually 14 days of life, but some experts would also test at birth, especially for newborns with mothers with unknown HIV status or who are not virologically suppressed). Testing should be repeated at 4 to 6 weeks of age and again at 4 to 6 months of age. A nucleic acid amplification test should be performed during this period, as antibody testing will reflect the mother's serologic status until the infant is older than 18 months. HIV DNA PCR may be preferable over HIV RNA PCR because the ARV prophylaxis may lower infant plasma viral RNA to undetectable levels. However, not all laboratories offer HIV DNA PCR. Also, not all HIV DNA PCR assays are able to detect non-subtype B or group O HIV, and so if this is a concern, both assays should be performed. Many experts will confirm an HIV-negative status with an HIV antibody test after age 18 months.

Infants are considered presumptively negative if they have had two negative nucleic acid amplification test results by age 4 to 6 weeks. More definitive testing is at the 4- to 6-month age mark. If the HIV status is unknown or not delineated by the time the prophylaxis course is complete at 4 to 6 weeks, infants should start prophylaxis for *Pneumocystis jirovecii* pneumonia.

HIV-infected mothers may have an increased incidence of coinfection with other pathogens that can be transmitted from mother to child. Pathogens to consider include HBV, HCV, *Treponema pallidum*, *Mycobacterium tuberculosis*, HSV, CMV, and *Toxoplasma gondii*. Infants may need additional testing depending on any known coinfections in the mother and the clinical history of the mother, including evidence of any of these diseases during the perinatal period. HBV vaccine may be given per the usual schedule and preferably within the first 12 hours of birth as the immunoprophylaxis of perinatal infection is most effective within this period. The routine primary immunization schedule may be followed thereafter. The schedule for live virus vaccines may need to be adjusted for infants identified as infected with HIV.

Human Immunodeficiency Virus–Infected Infant

If the result of a nucleic acid amplification test is positive, the test should be repeated for confirmation. Viral resistance testing should then be performed, and the ART regimen should be adjusted as

needed. Both genotypic and phenotypic resistance testing is available. Genotype testing reflects the actual genetic mutations that may or may not confer clinically important resistance. Phenotype testing measures the ability of a specific patient's virus to replicate while exposed to each individual ARV tested. This is compared with a "wild-type virus" control. Both types of tests should be performed if available, but either can provide resistance information needed to adjust an ART regimen if indicated.

With the more rapid turnaround of nucleic acid amplification tests, diagnoses are made earlier than previously experienced. There are very limited dosing and safety data for ARVs in the early newborn period.

There is growing interest in early and aggressive treatment with combination ART, especially in light of the so-called Mississippi baby case of an HIV-infected newborn in whom combination ART was started at 30 hours of life and who demonstrated a prolonged remission after ART was stopped against medical advice at age 18 months (Persaud et al., 2013). Viremia recurred, but there was 2 years of viral suppression despite the absence of ART. This has been attributed to the knowledge that HIV can hide in reservoirs despite an undetectable plasma viral load, and this may lead to rebound viremia (Luzuriaga et al., 2015). Despite cases like this, there is a lack of evidence to support the practice of very early treatment. We recommend consultation with a pediatric HIV specialist to determine the optimal regimen and dosing at the time of a confirmed positive nucleic acid amplification test result, especially in newborns less than 2 weeks old.

Zidovudine remains the only drug recommended for treatment of preterm infants. They may transition to therapy with another drug, or another drug may be added once they reach 14 days past their original due date. In term neonates, zidovudine, lamivudine, emtricitabine, and stavudine can be used for treatment starting at birth. Once the term neonates reach 14 days of age, didanosine, ritonavir-boosted lopinavir, and nevirapine can also be used.

Current dosing for nevirapine is based on the regimen used in the NICHD-HPTN 040 study. This was designed to target prophylaxis concentrations above 0.1 µg/mL rather than the 3.0 µg/mL target for treatment concentrations. A dosing regimen designed to reach the plasma target for therapeutic levels is currently under investigation in the IMPAACT P1115 clinical trial.

Summary

ARVs used during pregnancy, labor, and breastfeeding and for infant prophylaxis have dramatically reduced mother-to-child transmission of HIV. However, not all women and infants are offered ART, and not all have access to care. We can also identify infection in neonates earlier and more reliably with nucleic acid amplification tests, but not all infants at risk are tested. UNAIDS announced the "90-90-90" targets toward ending the AIDS epidemic by 2020: 90% of people with HIV will be diagnosed, 90% of those with a diagnosis will be receiving sustained ART, with 90% viral suppression in those receiving ART. Women and children are at the center of this campaign (Davies et al., 2015). Also, the programs initiated as part of the Global Plan "towards the elimination of new HIV infections among children and keeping their mothers alive" will continue. The National Institute for Allergy and Infectious Diseases announced plans for a new vaccine trial at HIV Vaccine Awareness Day 2016. This new trial (HVTN 702)

commenced in November, 2016, and plans to enroll 5400 subjects to assess the safety, tolerability, and effectiveness of a vaccine regimen designed to prevent acquisition of HIV infection in South African adults. This vaccine is based on a prime-boost regimen of two vaccines: ALVAC-HIV vaccine (the primer dose), a modified canarypox vaccine–vectored vaccine, and AIDSVAX B/E vaccine (the booster dose), a glycoprotein 120 vaccine. In a previous phase III study in Thailand (the RV144 study), this vaccine demonstrated an efficacy of 31% in prevention of HIV infection (Rerks-Ngarm et al., 2009).

Guidelines for the treatment of women during pregnancy, ART, infant prophylaxis, and pediatric ART change rapidly. We recommend readers also access the Web-based program AIDS Info (<https://aidsinfo.nih.gov>) of the US Department of Health and Human Services for the current guidelines and information.
